KEY POINTS

- Interest rate models are important tools for practitioners and are useful for pricing fixed income securities, valuing interest-rate contingent claims, and for risk management purposes.
- There exist many interest rate models. One factor models of the short rate make important assumptions about its dynamics through time. Understanding these assumptions and their implications is critical for practitioners.
- Interest rate models specify a stochastic differential equation to capture the dynamics of the models.
- Early models (Ho-Lee and Hull-White) assume the short rate is distributed normally. Interest rates in those models may be negative. Other models (Kalotay-Williams-Fabozzi, Black-Derman-Toy, and Black-Karasinski models) assume the short rate is distributed log-normally, restricting the short rate to be positive.
- Mean-reversion is the tendency for interest rates to tend toward a long-term target rate. Absent mean-reversion, an interest rate model may allow the short rate to grow unbounded.
- The no-arbitrage models incorporate the information in the current term structure and produce identical prices for option-free bonds.
- When pricing bonds with embedded option features, the interest rate model assumptions are critically important and may result in meaningful differences across different models.

The complication in building a model to value bonds with embedded options and option-type derivatives is that cash flows will depend on interest rates in the future. Academicians and practitioners have attempted to capture this interest rate uncertainty through various models, often designed as single or multi-factor models. These models attempt to capture the stochastic behavior of rates.

In practice, these elegant mathematical models must be converted to numeric applications. Here we focus on one such model—a single-factor model that assumes a stationary variance or, as it is more often called, volatility. We demonstrate how to move from the yield curve to a valuation lattice. Effectively, the lattice is a representation of the model, capturing the distribution of rates over time. In our illustration we will present the lattice as a binomial tree, the most simple lattice form.

The lattice holds all the information required to perform the valuation of certain option-like interest rate products. First, the lattice is used to generate cash flows over the life of the security. Next, the interest rates on the lattice are used to compute the present value of those cash flows.

There are several interest rate models that have been used in practice to construct an interest rate lattice. These are described in other chapters. In each case, interest rates can realize one of several possible rates when we move from one period to the next. A lattice model where it is assumed that only two rates are possible in the next period given the current rate is called a *binomial model*. A lattice model where it is assumed that interest rates can take on three possible rates

in the next period is called a *trinomial model*. There are even more complex models that assume more than three possible rates in the next period can be realized.

Regardless of the underlying assumptions, each model shares a common restriction. The interest rate tree generated must produce a value for an on-the-run optionless issue that is consistent with the current par yield curve. In effect, the value estimated by the model must be equal to the observed market price for the optionless instrument. Under these conditions, the model is said to be "arbitrage free." A lattice that produces an arbitrage-free valuation is said to be "fair." The lattice is used for valuation only when it has been calibrated to be fair. More on calibration below.

In this chapter we show how to value bonds with embedded options using the lattice methodology. We begin by demonstrating how an interest rate lattice is constructed. Then we use the model to value bonds with an embedded option. The lattice methodology also can be used to value floating-rate securities with option-type derivatives, options on bonds, caps, floors, swaptions, and forward-start swaps.[1]

THE INTEREST RATE LATTICE

Exhibit 40–1 provides an example of a binomial interest rate tree, which consists of a number of "nodes" and "legs." Each leg represents a one-year interval over time. A simplifying assumption of one-year intervals is made to illustrate the key principles. The methodology is the same for smaller time periods. In fact, in practice, the selection of the length of the time period is critical, but we need not be concerned with this nuance here.

The distribution of future interest rates is represented on the tree by the nodes at each point in time. Each node is labeled as N and has a subscript, a combination of L's and H's. The subscripts indicate whether the node is lower or higher on the tree, respectively, relative to the other nodes. Thus node N_{HH} is reached when the one-year rate realized in the first year is the higher of the two rates for that period, then the highest of the rates in the second year.

The root of the tree is N, the only point in time at which we know the interest rate with certainty. The one-year rate today (i.e., at N) is the current one-year spot rate, which we denote by r_0.

We must make an assumption concerning the probability of reaching one rate at a point in time. For ease of illustration, we have assumed that rates at any point in time have the same probability of occurring; in other words, the probability is 50% on each leg.

1. These applications of the lattice methodology are presented in Frank J. Fabozzi, Andrew Kalotay, and Michael Dorigan, "Yield Curves and Valuation Lattices" and "Using the Lattice Model to Value Bonds with Embedded Options, Floaters, Options, and Caps/Floors," Chapters 13 and 14 in Frank J. Fabozzi (ed.), *Interest Rate, Term Structure, and Valuation Modeling* (Hoboken, NJ: Wiley, 2002).

EXHIBIT 40–1

Four-Year Binomial Interest Rate Tree

The interest rate model we will use to construct the binomial tree assumes that the one-year rate evolves over time based on a log-normal random walk with a known (stationary) volatility. Technically, the tree represents a one-factor model. Under the distributional assumption, the relationship between any two adjacent rates at a point in time is calculated via the following equation:

$$r_{1,H} = r_{1,L}e^{2\sigma\sqrt{t}}$$

where σ is the assumed volatility of the one-year rate, t is time in years, and e is the base of the natural logarithm. Since we assume a one-year interval, that is, $t = 1$, we can disregard the calculation of the square root of t in the exponent.

For example, suppose that $r_{1,L}$ is 4.4448% and σ is 10% per year, then

$$r_{1,H} = 4.4448\%(e^{2\times 0.10}) = 5.4289\%$$

In the second year, there are three possible values for the one-year rate. The relationship between $r_{2,LL}$ and the other two one-year rates is as follows:

$$r_{2,HH} = r_{2,LL}\,(e^{4\sigma}) \qquad \text{and} \qquad r_{2,HL} = r_{2,LL}(e^{2\sigma})$$

EXHIBIT 40–2

Four-Year Binomial Interest Rate Tree with One-Year Rates*

*r_t is the lowest one-year rate at each point in time.

Thus, for example, if $r_{2,LL}$ is 4.6958%, and assuming once again that σ is 10%, then

$$r_{2,HH} = 4.6958\%(e^{4\times 0.10}) = 7.0053\%$$

and

$$r_{2,HL} = 4.6958\%(e^{2\times 0.10}) = 5.7354\%$$

This relationship between rates holds for each point in time. Exhibit 40–2 shows the interest rate tree using this new notation.

Determining the Value at a Node

In general, to get a security's value at a node, we follow the fundamental rule for valuation: The value is the present value of the expected cash flows. The appropriate discount rate to use for cash flows one year forward is the one-year rate at the node where we are computing the value. Now there are two present values in this case: the present value of the cash flows in the state where the one-year rate is the higher rate and one where it is the lower-rate state. We have assumed that the probability of

EXHIBIT 40–3

Calculating a Value at a Node

both outcomes is equal. Exhibit 40–3 provides an illustration for a node assuming that the one-year rate is r^* at the node where the valuation is sought and letting

V_H = the bond's value for the higher one-year rate state
V_L = the bond's value for the lower one-year rate state
C = coupon payment

From where do the future values come? Effectively, the value at any node depends on the future cash flows. The future cash flows include (1) the coupon payment one year from now and (2) the bond's value one year from now, both of which may be uncertain. Starting the process from the last year in the tree and working backwards to get the final valuation resolves the uncertainty. At maturity, the instrument's value is known with certainty—par. The final coupon payment can be determined from the coupon rate or from prevailing rates to which it is indexed. Working back through the tree, we realize that the value at each node is calculated quickly. This process of working backward is often referred to as *recursive valuation*.

Using our notation, the cash flow at a node is either

$V_H + C$ for the higher one-year rate
$V_L + C$ for the lower one-year rate

The present value of these two cash flows using the one-year rate at the node, r^*, is

$$\frac{V_H + C}{(1+r^*)} = \text{present value for the higher one-year rate}$$

$$\frac{V_L + C}{(1+r^*)} = \text{present value for the lower one-year rate}$$

Then the value of the bond at the node is found as follows:

$$\text{Value at a node} = \frac{1}{2}\left[\frac{V_H + C}{(1+r^*)} + \frac{V_L + C}{(1+r^*)}\right]$$

CALIBRATING THE LATTICE

We noted earlier the importance of the no-arbitrage condition that governs the construction of the lattice. To ensure that this condition holds, the lattice must be calibrated to the current par yield curve, a process we demonstrate here. Ultimately, the lattice must price optionless par bonds at par.

Assume the on-the-run par yield curve for a hypothetical issuer as it appears in Exhibit 40–4. The current one-year rate is known, 3.50%. Hence the next step is to find the appropriate one-year rates one year forward. As before, we assume that volatility σ is 10% and construct a two-year tree using the two-year bond with a coupon rate of 4.2%, the par rate for a two-year security.

Exhibit 40–5 shows a more detailed binomial tree with the cash flow shown at each node. The root rate for the tree r_0 is simply the current one-year rate, 3.5%. At the beginning of year 2, there are two possible one-year rates, the higher rate and the lower rate. We already know the relationship between the two. A rate of 4.75% at N_L has been chosen arbitrarily as a starting point. An iterative process determines the proper rate (i.e., trial-and-error). The steps are described and illustrated below. Again, the goal is a rate that, when applied in the tree, provides a value of par for the two-year 4.2% bond.

Step 1. Select a value for r_1. Recall that r_1 is the lower one-year rate. In this first trial, we arbitrarily selected a value of 4.75%.

Step 2. Determine the corresponding value for the higher one-year rate. As explained earlier, this rate is related to the lower one-year rate as follows: $r_1 e^{2\sigma}$. Since r_1 is 4.75%, the higher one-year rate is 5.8017% (= 4.75% $e^{2\times 0.10}$). This value is reported in Exhibit 40–5 at node N_H.

EXHIBIT 40–4

Issuer Par Yield Curve

Maturity	Par Rate	Market Price
1 year	3.50%	100
2 years	4.20%	100
3 years	4.70%	100
4 years	5.20%	100

EXHIBIT 40–5

The One-Year Rates for Year 1 Using the Two-Year 4.2% On-the-Run Issue: First Trial

Step 3. Compute the bond value's one year from now. This value is determined as follows:

a. Determine the bond's value two years from now. In our example, this is simple. Since we are using a two-year bond, the bond's value is its maturity value ($100) plus its final coupon payment ($4.2). Thus it is $104.2.

b. Calculate V_H. Cash flows are known. The appropriate discount rate is the higher one-year rate, 5.8017% in our example. The present value is $98.486 (= $104.2/1.058017).

c. Calculate V_L. Again, cash flows are known—the same as those in step 3b. The discount rate assumed for the lower one-year rate is 4.75%. The present value is $99.475 (= $104.2/1.0475).

Step 4. Calculate V.

a. Add the coupon to both V_H and V_L to get the cash flow at N_H and N_L, respectively. In our example we have $102.686 for the higher rate and $103.675 for the lower rate.

b. Calculate V. The one-year rate is 3.50%. (*Note:* At this point in the valuation, r^* is the root rate, 3.50%). Therefore, $99.691 = 1/2($99.214 + $100.169)

Step 5. Compare the value in step 4 to the bond's market value. If the two values are the same, then the r_1 used in this trial is the one we seek. If, instead, the value found in step 4 is not equal to the market value of the bond, this means that the value r_1 in this trial is not the one-year rate that is consistent with the current yield curve. In this case, the five steps are repeated with a different value for r_1.

When r_1 is 4.75%, a value of \$99.691 results in step 4, which is less than the observed market price of \$100. Therefore, 4.75% is too large, and the five steps must be repeated trying a lower rate for r_1.

Let's jump right to the correct rate for r_1 in this example and rework steps 1 through 5. This occurs when r_1 is 4.4448%. The corresponding binomial tree is shown in Exhibit 40–6. The value at the root is equal to the market value of the two-year issue (par).

We can "grow" this tree for one more year by determining r_2. Now we will use the three-year on-the-run issue, the 4.7% coupon bond, to get r_2. The same five steps are used in an iterative process to find the one-year rates in the tree two years from now. Our objective is now to find the value of r_2 that will produce a bond value of \$100. Note that the two rates one year from now of 4.4448% (the lower rate) and 5.4289% (the higher rate) do not change. These are the fair rates for the tree one-year forward.

The problem is illustrated in Exhibit 40–7. The cash flows from the three-year 4.7% bond are in place. All we need to perform a valuation are the rates at the start of year 3. In effect, we need to find r_2 such that the bond prices at par. Again, an arbitrary starting point is selected, and an iterative process produces the correct rate.

The completed version of Exhibit 40–7 is found in Exhibit 40–8. The value of r_2, or equivalently $r_{2,LL}$, that will produce the desired result is 4.6958%. The corresponding rates $r_{2,HL}$ and $r_{2,HH}$ would be 5.7354% and 7.0053%, respectively.

EXHIBIT 40–6

The One-Year Rates for Year 1 Using the Two-Year 4.2% On-the-Run Issue

EXHIBIT 40–7

Information for Deriving the One-Year Rates for Year 2 Using the Three-Year 4.7% On-the-Run Issue

EXHIBIT 40–8

The One-Year Rates for Year 2 Using the Three-Year 4.7% On-the-Run Issue

To verify that these are the correct one-year rates two years from now, work backwards from the four nodes at the right of the tree in Exhibit 40–8. For example, the value in the box at N_{HH} is found by taking the value of \$104.7 at the two nodes to its right and discounting at 7.0053%. The value is \$97.846. Similarly, the value in the box at N_{HL} is found by discounting \$104.70 by 5.7354% and at N_{LL} by discounting at 4.6958%.

USING THE LATTICE FOR VALUATION

To illustrate how to use the lattice for valuation purposes, consider a 6.5% option-free bond with four years remaining to maturity. Since this bond is option-free, it is not necessary to use the lattice model to value it. All that is necessary to obtain an arbitrage-free value for this bond is to discount the cash flows using the spot rates obtained from bootstrapping the yield curve shown in Exhibit 40–4. The spot rates are as follows:

1-year	3.5000%
2-years	4.2147%
3-years	4.7345%
4-years	5.2707%

Discounting the 6.5% four-year option-free bond with a par value of \$100 at the above spot rates would give a bond value of \$104.643.

Exhibit 40–9 contains the fair tree for a four-year valuation. Exhibit 40–10 shows the various values in the discounting process using the lattice in Exhibit 40–9. The root of the tree shows the bond value of \$104.643, the same value found by discounting at the spot rate. This demonstrates that the lattice model is consistent with the valuation of an option-free bond when using spot rates.

FIXED-COUPON BONDS WITH EMBEDDED OPTIONS

The valuation of bonds with embedded options proceeds in the same fashion as in the case of an option-free bond. However, the added complexity of an embedded option requires an adjustment to the cash flows on the tree depending on the structure of the option. A decision on whether to call or put must be made at nodes on the tree where the option is eligible for exercise. Examples for both callable and putable bonds follow.

Valuing a Callable Bond

In the case of a call option, the call will be made when the present value (PV) of the future cash flows is greater than the call price at the node where the decision to exercise is being made. Effectively, the following calculation is made:

$$V_t = \min[\text{call price, PV(future cash flows)}]$$

EXHIBIT 40–9

Binomial Interest Rate Tree for Valuing Up to a Four-Year Bond for Issuer (10% Volatility Assumed)

EXHIBIT 40–10

Valuing an Option-Free Bond with Four Years to Maturity and a Coupon Rate of 6.5% (10% Volatility Assumed)

where V_t represents the PV of future cash flows at the node. This operation is performed at each node where the bond is eligible for call.

For example, consider a 6.5% bond with four years remaining to maturity that is callable in one year at $100. We will value this bond, as well as the other instruments in this chapter, using a binomial tree. Exhibit 40–9 is the binomial interest rate tree that was derived earlier in this chapter and then used to value an option-free bond. In constructing the binomial tree in Exhibit 40–9, it is assumed that interest rate volatility is 10%. This binomial tree will be used throughout this chapter.

Exhibit 40–11 shows that two values are now present at each node of the binomial tree. The discounting process explained earlier is used to calculate the first of the two values at each node. The second value is the value based on whether the issue will be called. Again, the issuer calls the issue if the PV of future cash flows exceeds the call price. This second value is incorporated into the subsequent calculations.

In Exhibits 40–12 and 40–13, certain nodes from Exhibit 40–11 are highlighted. Exhibit 40–12 shows nodes where the issue is not called (based on the simple call rule used in the illustration) in years 2 and 3.[2] The values reported in this case are the same as in the valuation of an option-free bond. Exhibit 40–13 shows some nodes where the issue is called in years 2 and 3. Notice how the methodology changes the cash flows. In year 3, for example, at node N_{HLL} the recursive valuation process produces a PV of 100.315. However, given the call rule, this issue would be called. Therefore, 100 is shown as the second value at the node, and it is this value that is then used as the valuation process continues. Taking the process to its end, the value for this callable bond is 102.899.

The value of the call option is computed as the difference between the value of an optionless bond and the value of a callable bond. In our illustration, the value of the option-free bond is 104.643 (calculated earlier in this chapter). The value of the callable bond is 102.899. Hence the value of the call option is 1.744 (=104.634 – 102.899).

Valuing a Putable Bond

A putable bond is one in which the bondholder has the right to force the issuer to pay off the bond prior to the maturity date. The analysis of the putable bond follows closely that of the callable bond. In the case of the putable, we must establish the rule by which the decision to put is made. The reasoning is similar to that for the callable bond. If the PV of the future cash flows is less than the put price (i.e., par), then the bond will be put. In equation form,

$$V_t = \max[\text{put price, PV(future cash flows)}]$$

Exhibit 40–14 is analogous to Exhibit 40–3. It shows the binomial tree with the values based on whether or not the investor exercises the put option at each node.

2. We assume cash flows occur at the end of the year.

EXHIBIT 40–11

Valuing a Callable Bond with Four Years to Maturity, a Coupon Rate of 6.5%, and Callable after the First Year at 100 (10% Volatility Assumed)

EXHIBIT 40–12

Highlighting Nodes in Years 2 and 3 for a Callable Bond: Nodes Where Call Option Is Not Exercised

EXHIBIT 40–13

Highlighting Nodes in Years 2 and 3 for a Callable Bond: Selected Nodes Where the Call Option Is Exercised

EXHIBIT 40–14

Valuing a Putable Bond with Four Years to Maturity, a Coupon Rate of 6.5%, and Putable after the First Year at 100 (10% Volatility Assumed)

The bond is putable any time after the first year at par. The value of the bond is 105.327. Note that the value is greater than the value of the corresponding option-free bond.

With the two values in hand, we can calculate the value of the put option. Since the value of the putable bond is 105.327 and the value of the corresponding option-free bond is 104.643, the value of the embedded put option purchased by the investor is effectively 0.684.

Suppose that a bond is both putable and callable. The procedure for valuing such a structure is to adjust the value at each node to reflect whether the issue would be put or called. Specifically, at each node there are two decisions about the exercising of an option that must be made. If it is called, the value at the node is replaced by the call price. The valuation procedure then continues using the call price at that node. If the call option is not exercised at a node, it must be determined whether or not the put option will be exercised. If it is exercised, then the put price is substituted at that node and is used in subsequent calculations.

VALUATION OF TWO MORE EXOTIC STRUCTURES

The lattice-based recursive valuation methodology is robust. To further support this claim, we address the valuation of two more exotic structures—the step-up callable note and the range floater.

Valuing a Step-Up Callable Note

Step-up callable notes are callable instruments whose coupon rate is increased (i.e., "stepped up") at designated times. When the coupon rate is increased only once over the security's life, it is said to be a *single step-up callable note*. A *multiple step-up callable note* is a step-up callable note whose coupon is increased more than one time over the life of the security. Valuation using the lattice model is similar to that for valuing a callable bond described earlier except that the cash flows are altered at each node to reflect the coupon characteristics of a step-up note.

Suppose that a four-year step-up callable note pays 4.25% for two years and then 7.5% for two more years. Assume that this note is callable at par at the end of year 2 and year 3. We will use the binomial tree given in Exhibit 40–9 to value this note.

Exhibit 40–15 shows the value of the note if it were not callable. The valuation procedure is the now familiar recursive valuation from Exhibits 40–12 and 40–13. The coupon in the box at each node reflects the step-up terms. The value is 102.082. Exhibit 40–16 shows that the value of the single step-up callable note is 100.031. The value of the embedded call option is equal to the difference in the optionless step-up note value and the step-up callable note value, 2.051.

EXHIBIT 40–15

Valuing a Single Step-Up Noncallable Note with Four Years to Maturity (10% Volatility Assumed)

EXHIBIT 40–16

Valuing a Single Step-Up Callable Note with Four Years to Maturity, Callable in Two Years at 100 (10% Volatility Assumed)

EXHIBIT 40–17

Coupon Schedule (Bands) for a Range Note

	Year 1	Year 2	Year 3
Lower limit	3.00%	4.00%	5.00%
Upper limit	5.00%	6.25%	8.00%

Now we move to another structure where the coupon floats with a reference rate but is restricted. In this next case, a range is set in which the bond pays the reference rate when the rate falls within a specified range, but outside the range no coupon is paid.

Valuing a Range Note

A *range note* is a security that pays the reference rate only if the rate falls within a band. If the reference rate falls outside the band, whether the lower or upper boundary, no coupon is paid. Typically, the band increases over time.

To illustrate, suppose that the reference rate is, again, the one-year rate and the note has three years to maturity. Suppose further that the band (or coupon schedule) is defined as in Exhibit 40–17. Exhibit 40–18 holds our tree and the

EXHIBIT 40–18

Valuation of a Three-Year Range Floater

cash flows expected at the end of each year. Either the one-year reference rate is paid, or nothing. In the case of this three-year note, there is only one state in which no coupon is paid. Using our recursive valuation method, we can work back through the tree to the current value, 98.963.

EXTENSIONS

We next demonstrate how to compute the option-adjusted spread, effective duration, and the convexity for a fixed income instrument with an embedded option.

Option-Adjusted Spread

We have concerned ourselves with valuation to this point. However, financial market transactions determine the actual price for a fixed income instrument, not a series of calculations on an interest rate lattice. If markets are able to provide a meaningful price (usually a function of the liquidity of the market in which the instrument trades), this price can be translated into an alternative measure of value, the option-adjusted spread (OAS).

The OAS for a security is the fixed spread (usually measured in basis points) over the benchmark rates that equates the output from the valuation process with the actual market price of the security. For an optionless security, the calculation of OAS is a relatively simple, iterative process. The process is much more analytically challenging with the added complexity of optionality. And just as the value of the option is volatility-dependent, the OAS for a fixed income security with embedded options or an option-like interest-rate product is volatility-dependent.

Recall our illustration in Exhibit 40–11, where the value of a callable bond was calculated as 102.899. Suppose that we had information from the market that the price is actually 102.218. We need the OAS that equates the value from the lattice with the market price. Since the market price is lower than the valuation, the OAS is a positive spread to the rates in the exhibit, rates that we assume to be benchmark rates.

The solution in this case is 35 basis points, which is incorporated into Exhibit 40–19 that shows the value of the callable bond after adding 35 basis points to each rate. The simple binomial tree provides evidence of the complex calculation required to determine the OAS for a callable bond. In Exhibit 40–11, the bond is called at N_{HLL}. However, once the tree is shifted 35 basis points in Exhibit 40–19, the PV of future cash flows at N_{HLL} falls below the call price to 99.985, so the bond is not called at this node. Hence, as the lattice structure grows in size and complexity, the need for computer analytics becomes obvious.

EXHIBIT 40–19

Demonstration that the Option-Adjusted Spread Is 35 Basis Points for a 6.5% Callable Bond Selling at 102.218 (Assuming 10% Volatility)*

*Each one-year rate is 35 basis points greater than in Exhibit 40–11.

Effective Duration and Effective Convexity

Duration and convexity provide a measure of the interest rate risk inherent in a fixed income security. We rely on the lattice model to calculate the effective duration and effective convexity of a bond with an embedded option and other option-like securities. The formulas for these two risk measures are given below:

$$\text{Effective duration} = \frac{V_- - V_+}{2V_0(\Delta r)}$$

$$\text{Effective convexity} = \frac{V_+ + V_- - 2V_0}{2V_0(\Delta r)^2}$$

where V_- and V_+ are the values derived following a parallel shift in the yield curve down and up, respectively, by a fixed spread. The model adjusts for the changes in the value of the embedded call option that result from the shift in the curve in the calculation of V_- and V_+.

Note that the calculations must account for the OAS of the security. Below we provide the steps for the proper calculation of V_+. The calculation for V_- is analogous.

Step 1. Given the market price of the issue, calculate its OAS.

Step 2. Shift the on-the-run yield curve up by a small number of basis points (Δr).

Step 3. Construct a binomial interest-rate tree based on the new yield curve from step 2.

Step 4. Shift the binomial interest-rate tree by the OAS to obtain an "adjusted tree." That is, the calculation of the effective duration and convexity assumes a constant OAS.

Step 5. Use the adjusted tree in step 4 to determine the value of the bond, V_+.

We can perform this calculation for our four-year callable bond with a coupon rate of 6.5%, callable at par selling at 102.218. We computed the OAS for this issue as 35 basis points. Exhibit 40–20 holds the adjusted tree following a shift in the yield curve up by 25 basis points and then adding 35 basis points (the OAS) across the tree. The adjusted tree is then used to value the bond. The resulting value V_+ is 101.621.

To determine the value of V_-, the same five steps are followed except that in step 2, the on-the-run yield curve is shifted down by a small number of basis points (Δr). It can be demonstrated that for our callable bond, the value for V_- is 102.765.

The results are summarized below:

$$\Delta r = 0.0025$$
$$V_+ = 101.621$$
$$V_- = 102.765$$
$$V_0 = 102.218$$

Therefore,

$$\text{Effective duration} = \frac{102.765 - 101.621}{2(102.218)(0.0025)} = 2.24$$

$$\text{Effective convexity} = \frac{101.621 + 102.765 - 2(102.218)}{2(102.218)(0.0025)^2} = -39.1321$$

Notice that this callable bond exhibits negative convexity.

EXHIBIT 40–20

Determination of V_+ for Calculating Effective Duration and Convexity*

*+25 basis point shift in on-the-run yield curve.

KEY POINTS

- For bonds with embedded options, the expected cash flow will depend on future interest-rate levels, which in turn depend on expected interest-rate volatility.
- An interest rate lattice provides a robust means for the valuation of a number of fixed income securities and derivatives.
- Given the market price of a bond, a lattice model can be used to obtain the option-adjusted spread to a benchmark yield curve based on an assumed interest rate volatility.

- A bond's OAS is the fixed spread (usually measured in basis points) over the benchmark rates that equates the output from the valuation process with the actual market price of the security.
- Effective duration and convexity can be computed for a bond by changing the yield-curve up and down by a given number of basis points and calculating what the new prices would be on the revised interest rate tree. These new prices are then used in the standard duration and convexity formula.

CHAPTER
FORTY-ONE

VALUATION OF AGENCY MORTGAGE-BACKED SECURITIES

FRANK J. FABOZZI, PH.D., CFA, CPA

Director, Fixed Income Investment Department
Morgan Stanley Huaxin Fund Management Company Limited

The traditional approach to the valuation of fixed income securities is to calculate yield—the yield-to-maturity, the yield-to-call for a callable bond, and the cash-flow yield for a mortgage-backed security. A superior approach is the option-adjusted spread (OAS) method. Our objective in this chapter is to describe the OAS method as applied to mortgage-backed securities. At the end of the chapter, we apply the method to two agency collateralized mortgage obligation (CMO) deals.

In this chapter we describe the theoretical foundations of this technique, the input and assumptions that go into the development of an OAS model, and the output of an OAS model, which in addition to the OAS value includes the option-adjusted duration and option-adjusted convexity. Because the user of an OAS model is exposed to *modeling risk,* it is necessary to test the sensitivity of these numbers to changes in the assumptions.

Valuation modeling for CMOs is similar to valuation modeling for pass-throughs, although the difficulties are amplified because the issuer has sliced and diced both the prepayment risk and the interest-rate risk into smaller pieces called *tranches*. The sensitivity of the pass-through securities from which the CMO is created to these two risks is not transmitted equally to every tranche. Some of the tranches wind up more sensitive to prepayment risk and interest-rate risk than the collateral, whereas some of them are much less sensitive.

The objective of the money manager is to figure out how the OAS of the collateral or, equivalently, the value of the collateral gets transmitted to the

CMO tranches. More specifically, the objective is to find out where the value goes and where the risk goes so that the money manager can identify the tranches with low risk and high value: the ones he wants to buy. The good news is that this combination usually exists in every deal. The bad news is that in every deal there are usually tranches with low OAS, low value, and high risk.

STATIC VALUATION

Using OAS to value mortgages is a dynamic technique in that many scenarios for future interest rates are analyzed. Static valuation analyzes only a single-interest-rate scenario, usually assuming that the yield-curve remains unchanged. Static valuation results in two measures, average life and static spread, which we review below.

Average Life

The *average life* of a mortgage-backed security is the weighted average time to receipt of principal payments (scheduled payments and projected prepayments). The formula for the average life is

$$\frac{1(\text{principal at time } 1) + \cdots + T(\text{principal at time } T)}{12(\text{total principal received})}$$

where T is the number of months.

In order to calculate average life, an investor must either assume a prepayment rate for the mortgage security being analyzed or use a prepayment model. By calculating the average life at various prepayment rates, the investor can gain some feeling for the stability of the security's cash-flows. For example, a PAC bond's average life will not change within the PAC bands but may shorten significantly if the prepayment rate exceeds the upper band. By examining the average life at prepayment rates greater than the upper band, an investor can judge some of the PAC's risks. With a prepayment model available, the average life of a mortgage security can be calculated by changing the mortgage refinancing rate. As the refinancing rate rises, the prepayment model will slow the prepayment rate and thus cause the bond's average life to extend. Conversely, if the refinancing rate is lowered, the model will cause prepayments to rise and shorten the average life.

Static Spread

One of the standard measures in evaluating any mortgage-backed security is the cash-flow yield, or simply "yield." The yield spread, sometimes called the *nominal spread,* is found by spreading the yield to the average life on the interpolated swap yield-curve. This practice is improper for an amortizing bond even in the absence of interest-rate volatility. Note that since late 1998, structured products are using swaps instead of Treasuries for pricing and hedging purposes. The main reason is that spread to swaps is more stable than to Treasuries.

What should be done instead is to calculate what is called the *static spread*. This is the yield spread in a static scenario (i.e., no volatility of interest rates) of the bond over the entire theoretical swap spot-rate curve, not a single point on the swap yield-curve. The magnitude of the difference between the nominal spread and the static yield depends on the steepness of the yield-curve: The steeper the curve, the greater the difference between the two values. In a relatively flat interest-rate environment, the difference between the nominal spread and the static spread will be small.

There are two ways to compute the static spread. One way is to use today's yield-curve to discount future cash-flows and keep the mortgage refinancing rate fixed at today's mortgage rate. Since the mortgage refinancing rate is fixed, the investor usually can specify a reasonable prepayment rate for the life of the security. Using this prepayment rate, the bond's future cash-flow can be estimated. Use of this approach to calculate the static spread recognizes different prices today of dollars to be delivered at future dates. This results in the proper discounting of cash-flows while keeping the mortgage rate fixed. Effectively, today's prices indicate what the future discount rates will be, but the best estimates of future rates are today's rates.

The second way to calculate the static spread allows the mortgage rate to go up the curve as implied by the forward interest rates. This procedure is sometimes called the *zero-volatility OAS*. In this case, a prepayment model is needed to determine the vector of future prepayment rates implied by the vector of future refinancing rates. A money manager using static spread should determine which approach is used in the calculation.

DYNAMIC VALUATION MODELING

Because CMOs are simply a regrouping of the cash-flows from the underlying pass-through securities, the valuation of CMO tranches follows directly from the valuation of pass-through securities.

Using Simulation to Generate Interest-Rate Paths and Cash-Flows

A technique known as *simulation* is used to value complex securities such as mortgage-backed securities. Simulation is used because the monthly cash-flows are path-dependent. This means that the cash-flows received this month are determined not only by the current and future interest-rate levels but also by the path that interest rates took to get to the current level.

There are typically two sources of path dependency in a CMO tranche's cash-flows. First, collateral prepayments are path-dependent because this month's prepayment rate depends on whether there have been prior opportunities to refinance since the underlying mortgages were issued. Second, the cash-flow to be received this month by a CMO tranche depends on the outstanding balances of the other tranches in the deal. We need the history of prepayments to calculate these balances.

Conceptually, the valuation of pass-through securities using the simulation method is simple. In practice, however, it is very complex. The simulation involves generating a set of cash-flows based on simulated future mortgage refinancing rates, which, in turn, imply simulated prepayment rates.

The typical model that Wall Street firms and commercial vendors use to generate these random interest-rate paths takes as input today's term structure of interest rates and a volatility assumption. The term structure of interest rates is the theoretical spot-rate (or zero-coupon) curve implied by today's swap rates. The volatility assumption determines the dispersion of future interest rates in the simulation. The simulations should be normalized so that the average simulated price of a zero-coupon swap equals today's actual price.

Each OAS model has its own model of the evolution of future interest rates and its own volatility assumptions. Until recently, there have been few significant differences in the interest-rate models of dealer firms and OAS vendors, although their volatility assumptions can be significantly different. Note that the volatility in term structure models is calibrated to the prices of liquid securities that reflect at-the-money options on interest rates, such as at-the-money caps and swaptions, as well as off-the-money swaptions (to capture the volatility skew).

The random paths of interest rates should be generated from an arbitrage-free model of the future term structure of interest rates. By arbitrage-free it is meant that the model replicates today's term structure of interest rates, an input of the model, and that for all future dates there is no possible arbitrage within the model.[1]

The simulation works by generating many scenarios of future interest-rate paths. In each month of the scenario, a monthly interest rate and a mortgage refinancing rate are generated. The monthly interest rates are used to discount the projected cash-flows in the scenario. The mortgage refinancing rate is needed to determine the cash-flow because it represents the opportunity cost the mortgagor is facing at that time.

If the refinancing rates are high relative to the mortgagor's original coupon rate, the mortgagor will have less incentive to refinance or even a disincentive (i.e., the homeowner will avoid moving in order to avoid refinancing). If the refinancing rate is low relative to the mortgagor's original coupon rate, the mortgagor has an incentive to refinance.

Prepayments are projected by feeding the refinancing rate and loan characteristics, such as age, into a prepayment model. Given the projected prepayments, the cash-flow along an interest-rate path can be determined.

To make this more concrete, consider a newly issued mortgage pass-through security with a maturity of 360 months. Exhibit 41–1 shows N simulated interest-rate path scenarios. Each scenario consists of a path of 360 simulated one-month future interest rates. Just how many paths should be generated is explained later.

1. A risk-neutral, arbitrage-free model of Treasury yields means that at all future dates the price of any long-term bond equals the expected value of rolling short-term to maturity. For more details, see Fischer Black, Emmanuel Derman, and William Toy, "A One-Factor Model of Interest Rates and its Application to Treasury Bond Options," *Financial Analyst Journals* (January–February 1990), pp. 33–39.

358	$C_{358}(1)$	$C_{358}(2)$	$C_{358}(3)$	. . .	$C_{358}(n)$	. . .	$C_{358}(N)$
359	$C_{359}(1)$	$C_{359}(2)$	$C_{359}(3)$	. . .	$C_{359}(n)$	. . .	$C_{359}(N)$
360	$C_{360}(1)$	$C_{360}(2)$	$C_{360}(3)$	. . .	$C_{360}(n)$	. . .	$C_{360}(N)$

Notation:
$C_t(n)$ = cash-flow for month t on path n
N = total number of interest-rate paths

rate on a path can be determined from the simulated future monthly rates. The relationship that holds between the simulated spot rate for month T on path n and the simulated future one-month rates is

$$z_T(n) = \{[1 + f_1(n)][1 + f_2(n)] \cdots [1 + f_T(n)]\}^{1/T} - 1$$

where

$z_T(n)$ = simulated spot rate for month T on path n
$f_j(n)$ = simulated future one-month rate for month j on path n

Consequently, the interest-rate path for the simulated future one-month rates can be converted to the interest-rate path for the simulated monthly spot rates, as shown in Exhibit 41–4. Therefore, the present value of the cash-flow for month T on interest-rate path n discounted at the simulated spot rate for month T plus some spread is

$$\text{PV}[C_T(n)] = \frac{C_T(n)}{[1 + z_T(n) + K]^{1/T}}$$

where

PV$[C_T(n)]$ = present value of cash-flow for month T on path n
$C_T(n)$ = cash-flow for month T on path n
$z_T(n)$ = spot rate for month T on path n
K = spread

The present value for path n is the sum of the present value of the cash-flow for each month on path n. That is,

$$\text{PV}[\text{path}(n)] = \text{PV}[C_1(n)] + \text{PV}[C_2(n)] + \cdots + \text{PV}[C_{360}(n)]$$

where PV[path(n)] is the present value of interest-rate path n.

359	$z_{359}(1)$	$z_{359}(2)$	$z_{359}(3)$	. . .	$z_{359}(n)$	. . .	$z_{359}(N)$
360	$z_{360}(1)$	$z_{360}(2)$	$z_{360}(3)$	. . .	$z_{360}(n)$	. . .	$z_{360}(N)$

Notation:
$z_t(n)$ = spot rate for month t on path n
N = total number of interest-rate paths

The option-adjusted spread is the spread K that when added to all the spot rates on all interest-rate paths will make the average present value of the paths equal to the observed market price (plus accrued interest). Mathematically, OAS is the spread K that will satisfy the following condition:

$$\text{Market price} = \frac{\text{PV[path(1)]} + \text{PV[path(2)]} + \cdots + \text{PV[path}(N)]}{N}$$

where N is the number of interest-rate paths.

This procedure for valuing a pass-through is also followed for a CMO tranche. The cash-flow for each month on each interest-rate path is found according to the principal repayment and interest distribution rules of the deal. In order to do this, a CMO structuring model is needed.

Selecting the Number of Interest-Rate Paths

Let's now address the question of the number of scenario paths or repetitions N needed to value a CMO tranche. A typical OAS run will be done for 512 to 1,024 interest-rate paths. The scenarios generated using the simulation method look very realistic and furthermore reproduce today's swap curve. By employing this technique, the money manager is effectively saying that swaps are fairly priced today and that the objective is to determine whether a specific tranche is rich or cheap relative to swaps.

The number of interest-rate paths determines how "good" the estimate is, not relative to the truth but relative to the OAS model used. The more paths, the more average spread tends to settle down. It is a statistical sampling problem.

Most OAS models employ some form of *variance reduction* to cut down on the number of sample paths necessary to get a good statistical sample.[2] Variance reduction techniques allow us to obtain price estimates within a tick. By this we mean that if the OAS model is used to generate more scenarios, price estimates from the model will not change by more than a tick. Thus, for example, if 1,024 paths are used to obtain the estimated price for a tranche, there is little more information to be had from the OAS model by generating more than that number of paths. (For some very sensitive CMO tranches, more paths may be needed to estimate prices within one tick.)

Interpretation of the OAS

The procedure for determining the OAS is straightforward, although time-consuming. The next question, then, is how to interpret the OAS. Basically, the OAS is used to reconcile value with market price. On the left-hand side of the last equation is the market's statement: The price of a mortgage-backed security or mortgage derivative. The average present value over all the paths on the right-hand side of the equation is the model's output, which we refer to as *value*.

What a money manager seeks to do is to buy securities whose value is greater than their price. A valuation model such as the one described earlier allows a money manager to estimate the value of a security, which at this point would be sufficient to determine whether to buy a security. That is, the money manager can say that this bond is 1 point cheap or 2 points cheap, and so on. The model does not stop here, however. Instead, it converts the divergence between price and value into a yield spread measure because most market participants find it more convenient to think about yield spread than about price differences.

The OAS was developed as a measure of the yield spread that can be used to reconcile dollar differences between value and price. But what is it a "spread" over? In describing the preceding model, we can see that the OAS is measuring the average spread over the swap spot-rate curve, not the swap yield-curve. It is an average spread because the OAS is found by averaging over the interest-rate paths for the possible spot-rate curves.

Option Cost

The implied cost of the option embedded in any mortgage-backed security can be obtained by calculating the difference between the OAS at the assumed volatility of interest rates and the static spread. That is,

$$\text{Option cost} = \text{static spread} - \text{option-adjusted spread}$$

2. For a discussion of variance reduction, see Phelim P. Boyle, "Options: A Monte Carlo Approach," *Journal of Financial Economics* 4 (1977), pp. 323–338.

The reason that the option cost is measured in this way is as follows: In an environment of no interest-rate changes, the investor would earn the static spread. When future interest rates are uncertain, the spread is less, however, because of the homeowner's option to prepay; the OAS reflects the spread after adjusting for this option. Therefore, the option cost is the difference between the spread that would be earned in a static interest-rate environment (the static spread) and the spread after adjusting for the homeowner's option.

In general, a tranche's option cost is more stable than its OAS in the face of market movements. This interesting feature is useful in reducing the computational expensive costs of calculating the OAS as the market moves. For small market moves, the OAS of a tranche may be approximated by recalculating the static spread (which is relatively cheap and easy to calculate) and subtracting its option cost.

Other Products of the OAS Models

Other products of the valuation model are option-adjusted duration, option-adjusted convexity, and simulated average life.

Option-Adjusted Duration

In general, duration measures the price sensitivity of a bond to a small change in interest rates. Duration can be interpreted as the approximate percentage change in price for a 100 basis point parallel shift in the yield-curve. For example, if a bond's duration is 4, this means a 100 basis point increase in interest rates will result in a price decrease of approximately 4%. A 50 basis point increase in yields will decrease the price by approximately 2%. The smaller the change in basis points, the better the approximated change in price will be.

The duration for any security can be approximated as follows:

$$\text{Duration} = \frac{P_- - P_+}{2P_0\Delta y}$$

where

P_- = price if yield is decreased (per \$100 of par value) by Δy
P_+ = price if yield is increased (per \$100 of par value) by Δy
P_0 = initial price (per \$100 of par value)
Δy = number of basis points change used to calculate P_- and P_+

The standard measure of duration is modified duration. The limitation of modified duration is that it assumes that if interest rates change, the cash-flow does not change. While modified duration is fine for option-free securities such as Treasury bonds, it is inappropriate for mortgage-backed securities because projected cash-flows change as interest rates and prepayments change. When prices in the duration formula are calculated assuming that the cash-flow changes when interest rates change, the resulting duration is called *effective duration*.

Effective duration can be computed using an OAS model as follows: First, the bond's OAS is found using the current term structure of interest rates. Next, the bond is repriced holding OAS constant but shifting the term structure. Two shifts are used; in one, yields are increased, and in the second, they are decreased. This produces the two prices, P_- and P_+, used in the preceding formula. Effective duration calculated in this way is often referred to as *option-adjusted duration,* or *OAS duration.*

The assumption in using modified or effective duration to project the percentage price change is that all interest rates change by the same number of basis points; that is, there is a parallel shift in the yield-curve. If the term structure does not change by a parallel shift, then effective duration will not correctly predict the change in a bond's price.

Option-Adjusted Convexity

The convexity measure of a security is the approximate change in price that is not explained by duration. *Positive convexity* means that if yields change by a given number of basis points, the percentage increase in price will be greater than the percentage decrease in price. *Negative convexity* means that if yield changes by a given number of basis points, the percentage increase in price will be less than the percentage decrease in price. That is, for a 100 basis point change in yield:

Type of Convexity	Increase in Price	Decrease in Price
Positive convexity	*X*%	Less than *X*%
Negative convexity	*X*%	More than *X*%

Obviously, positive convexity is a desirable property of a bond. A pass-through security can exhibit either positive or negative convexity depending on the prevailing mortgage rate relative to the rate on the underlying mortgage loans. When the prevailing mortgage rate is much higher than the mortgage rate on the underlying mortgage loans, the pass-through usually exhibits positive convexity. It usually exhibits negative convexity when the underlying coupon rate is near or above prevailing mortgage refinancing rates.

The convexity of any bond can be approximated using the formula

$$\frac{P_+ + P_- - (P_0)}{2P_0(\Delta y)^2}$$

When the prices used in this formula assume that the cash-flows do not change when yields change, the resulting convexity is a good approximation of the standard convexity for an option-free bond. When the prices used in the formula are derived by changing the cash-flows (by changing prepayment rates)

when yields change, the resulting convexity is called *effective convexity*. Once again, when an OAS model is used to obtain the prices, the resulting value is referred to as the *option-adjusted convexity,* or *OAS convexity*.

Simulated Average Life

The average life reported in an OAS model is the average of the average lives along the interest-rate paths. That is, for each interest-rate path, there is an average life. The average of these average lives is the average life reported in an OAS model.

Additional information is conveyed by the distribution of the average life. The greater the range and standard deviation of the average life, the more uncertainty there is about the tranche's average life.

ILLUSTRATIONS

We use two deals to show how CMOs can be analyzed using the OAS methodology: a plain-vanilla sequential-pay structure and a PAC/support structure.

Plain-Vanilla Sequential-Pay Structure

As the name suggests, CMO tranches in a sequential-pay structure are amortized in sequence. The sequential-pay structure partitions the underlying mortgage collateral into bonds of varying maturities and durations, but does not allow the optionality of the bonds to be tailored.

The plain-vanilla sequential-pay CMO bond structure in our illustration is FHLMC 3145, Collateral Group 5 analyzed as of June 7, 2007. The focus of our analysis is tranches AB, AC, and AJ. Exhibit 41–5 shows the swap yield spread and volatility curve at the evaluation date.

Panel A of Exhibit 41–6 shows the OAS and the option cost for the collateral and the three tranches in the CMO structure. The OAS for the collateral is 24 basis points. Since the option cost is 32 basis points, the static spread is 56 basis points (24 basis points plus 32 basis points). As can be seen from Panel A of Exhibit 41–5, at the time this analysis was performed, the swap curve was not steep. As we noted earlier, in such a yield-curve environment, the static spread will not differ significantly from the traditionally computed yield spread. Thus, for the three tranches shown in Exhibit 41–6, the static spread is 27 for AB, 36 for B, and 52 for C. Notice that the tranches did not share the OAS equally. The same is true for the option cost. The value tended to go toward the longer bonds, something that occurs in the typical deal. Both the static spread and the option cost increase as the maturity increases. Notice that by purchasing tranches with the higher OAS, the manager is accepting greater interest rate risk as measured by the tranche's effective duration.

Now let's look at modeling risk. Examination of the sensitivity of the tranches to changes in prepayments and interest rate volatility will help us to understand the interaction of the tranches in the structure and who is bearing the risk.

EXHIBIT 41–5

Par Curve and Volatility Curve as of 6/7/2007

a. Swap curve

Years	Swap
0.25	5.35
0.5	5.39
1	5.47
2	5.45
3	5.47
4	5.51
5	5.55
7	5.62
10	5.70
20	5.83
30	5.85

Note: The swap curve is obtained from the Citigroup's proprietary trading group, fitted to key swap rates.

b. Volatility Curve

Option on 6-Month EDF		7.19	
Libor Cap Volatility		Swaptions Volatility	
1-Year	6.58	3M × 10	12.49
2-Year	11.05	1 × 10	12.11
3-Year	12.51	3 × 10	12.74
4-Year	13.16	5 × 10	12.61
5-Year	13.5	7 × 10	12.17
7-Year	13.75	10 × 10	11.57
10-Year	13.67	20 × 10	10.69

We begin with prepayments. Specifically, we keep the same interest-rate paths as those used to get the OAS in the base case (the top panel of Exhibit 41–6), but reduce the prepayment rate on each interest-rate path to 80% of the projected rate.

As can be seen in Panel B of Exhibit 41–6, slowing down prepayments decreases the OAS and price for the collateral. This is so because the collateral is trading below par value. Tranches created by this collateral typically will behave the same way. However, if a tranche was created with a higher coupon, allowing it to trade below above, then it may behave in the opposite fashion. The exhibit reports two results of the sensitivity analysis. First, it indicates the change in the

EXHIBIT 41–6

OAS Analysis of FHLMC 3145 Classes AB, AC, and AJ (as of 6/7/2007)

A. Base case (market-implied interest-rate volatility)

	OAS (bp)	Option Cost (bp)	Effective Duration	Static Spread
Collateral	24	32	5.3	56
AB	12	15	1.9	27
AC	14	22	4.3	36
AJ	20	32	8.4	52

B. Prepayments at 80% and 120% of Prepayment Model

	New OAS		Chg in Price (ticks)		Eff. Dur	
	80%	120%	80%	120%	80%	120%
Collateral	19	30	–10	9	5.8	5.0
AB	12	12	0	0	1.9	1.9
AC	9	17	–7	5	4.5	4.1
AJ	15	26	–14	13	9.0	7.9

C. ± 4% interest-rate volatility

	New OAS		Chg in Price (ticks)		Eff. Dur	
	–4%	+4%	–4%	+4%	–4%	+4%
Collateral	41	19	17	–19	5.6	5.2
AB	12	12	0	0	1.9	1.9
AC	18	10	5	–5	4.3	4.2
AJ	30	8	26	–30	8.6	8.2

D. Diagram of Principal Payment

OAS. Second, it indicates the change in the price, holding the OAS constant at the base case.

To see how a money manager can use the information in Panel B, consider tranche AC. At 80% of the prepayment speed, the OAS for this tranche decreases from 14 basis points to 9 basis points. If the OAS is held constant, the panel indicates that the buyer of tranche AC would lose $0.07 per $100 par value.

Notice that for the tranches AC and AJ reported in Exhibit 41–6, there is a loss from a slowdown in prepayments. This is so because all the sequential tranches in this deal were priced below par. Tranche AB's OAS and price are not impacted by a slowdown in prepayments.

Also shown in Panel B of the exhibit is the second part of our experiments to test the sensitivity of prepayments: The prepayment rate is assumed to be 120% of the base case. The collateral's price increases in this scenario because it is trading below par. This is reflected in the OAS of the collateral, which increases from 24 to 30 basis points.

Now look at the three tranches. Tranche AB's price and OAS did not change. Hence, this tranche is prepayment insensitive from 80% to 120% of the base case. The OAS and price of the other two tranches increased.

Now let's look at the sensitivity to the interest-rate volatility assumption. Two experiments are performed: reducing the volatility assumption to 4% of the base case and increasing it to 4% of the base case. These results are reported in Panel C of Exhibit 41–6. Reducing the volatility increases the dollar price of the collateral by $0.17 and increases the OAS from 24 to 41 basis points in the base case. This $0.17 increase in the price of the collateral is not equally distributed, however, among the three tranches. None of the increase went to tranche AC. Most of the increase in value is realized by the longest tranche, tranche AJ.

The OAS gain for each of the tranches follows more or less the effective durations of those tranches. This makes sense because the longer the duration, the greater the interest rate risk, and when volatility declines, the reward is greater for the accepted risk.

At the higher level of assumed interest-rate volatility, the collateral is adversely affected with the collateral's loss distributed among the tranches in the expected manner: the longer the effective duration, the greater the loss.

Using the OAS methodology, a fair conclusion that can be made about this simple plain-vanilla structure is: What you see is what you get. A money manager willing to extend duration gets paid for that risk in this plain-vanilla structure.

PAC/Support Bond Structure

PAC structures are designed to create a stable set of bonds by directing the prepayment risk of the underlying collateral to other bonds (the supports) in the structure. One set of bonds (the PACs) is assigned a principal redemption schedule, which is given priority over principal payments to the remaining bonds (the supports) in the structure.

Now let's look at how to apply the OAS methodology to a more complicated CMO structure, FHLMC 3104, Collateral Group 1. This $250 million agency CMO deal was issued on January 30, 2006 and analyzed on June 7, 2007 (so the interest-rate environment was that shown in Exhibit 41–5). A summary of the deal is provided in Exhibit 41–7. A diagram of the principal allocation is given in Exhibit 41–8. Shown in parentheses after each tranche's name in Exhibit 41–7 is the type of tranche. There are five planned amortization class (PAC) tranches that are sequential-pay PACs and they have the high structural priority, as shown

EXHIBIT 41–7

Summary of FHLMC 3104, Collateral Group 1

Total issue:	250,000,000	Original settlement date:	2/28/2006
Issue date:	1/30/2006	Days delay:	30
Structure type:	REMIC CMO	Payment frequency:	Monthly; 15th day of month
Issuer class:	Agency		
Dated date:	2/1/2006		

Tranche	Original Balance ($)	Coupon (%)	Stated Maturity	Average Life (yrs)	100% Prepayment Model Expected Maturity
QA (PAC)	71,655,780	5.00	10/15/2025	1.9	3/15/2011
QB (PAC)	25,372,498	5.00	1/15/2029	5.0	11/15/2013
QC (PAC)	25,633,676	5.00	9/15/2031	8.1	4/15/2017
QD (PAC)	31,839,817	5.00	5/15/2034	12.1	1/15/2022
QE (PAC)	24,132,798	5.00	1/15/2036	17.7	11/15/2035
FA (FLT, SUP)	9,074,584	0.84	6/15/2033	1.4	Paid down
SA (INV, SUP)	3,629,834	15.39	6/15/2033	1.4	Paid down
HA (SUP)	10,000,000	5.00	6/15/2033	1.5	Paid down
HB (SUP)	20,525,844	6.00	11/15/2017	2.3	Paid down
HO (PO, SUP)	8,105,169	0.00	1/15/2036	6.4	7/15/2034
HZ (SUP)	20,000,000	6.00	1/15/2036	8.8	7/15/2034

EXHIBIT 41–8

Diagram of Principal Allocation Structure of FHLMC 3104 Collateral Group 1 (as of 6/7/2007)

in Exhibit 41–8, while the other tranches are support bonds that have the low structural priority. Our focus will be on the five PAC tranches and the support tranches HO and HZ. We do not look at the floater and inverse floater support tranches (FA and SA, respectively).

Panel A of Exhibit 41–9 shows the base case OAS and the option cost for the collateral and all the tranches. The collateral OAS is 12 basis points, and the option cost is 28 basis points. The static spread of the collateral is 40 basis points. The 12 basis points of OAS did not get equally distributed among the tranches, as was the case with the plain-vanilla structure. Notice the high OAS for tranche HO the support principal-only tranche: 513 basis points. This tranche's option cost is –83 basis points, suggesting that this tranche, according to the model, is cheap. For the sequential-pay PAC tranches we see that the longer the effective duration, the higher the OAS.

The next two panels in Exhibit 41–9 show the sensitivity of the OAS and the price (holding OAS constant at the base case) to changes in the prepayment speed (80% and 120% of the base case) and to changes in volatility (±4% of the base case). With respect to sensitivity to prepayments, the short-term PAC tranche QA and support bond HZ are insensitive for the prepayment range tested. For all of the other tranches, the OAS and price decrease with a decrease in prepayments. The opposite holds for an increase in prepayments.

The sensitivity of the collateral and the tranches to changes in volatility are shown in Panel C of Exhibit 41–9. The shorter-term PAC tranche (QA) is insensitive to changes in volatility. However, unlike with prepayments, support tranche HZ is sensitive to interest-rate volatility. For all of the tranches except tranche HO, OAS and price increase with a decline in volatility and decrease with an increase in volatility.

EXHIBIT 41–9

OAS Analysis of FHLMC 3104 Collateral Group 1 (as of 6/7/2007)

A. Base case (market-implied interest-rate volatility)

	OAS (bp)	Option Cost (bp)	Effective Duration	Static Spread
Collateral	12	28	6.2	40
QA (PAC)	26	15	1.7	41
QB (PAC)	47	18	4.3	65
QC (PAC)	54	24	6.3	78
QD (PAC)	57	25	8.3	82
QE (PAC)	60	24	10.5	84
HO (SUP PO)	513	–83	6.0	430
HZ (SUP)	55	40	5.1	95

B. Prepayments at 80% and 120% of prepayment Model

	New OAS		Chg in Price (ticks)		Eff. Dur	
	80%	120%	80%	120%	80%	120%
Collateral	6	20	–13	12	6.6	5.9
QA (PAC)	26	26	0	0	1.7	1.7
QB (PAC)	41	53	–9	7	4.4	4.1
QC (PAC)	43	64	–21	17	6.7	6.0
QD (PAC)	48	66	–23	19	8.8	7.9
QE (PAC)	55	65	–14	12	11.0	10.1
HO (SUP PO)	480	555	–22	27	5.2	6.6
HZ (SUP)	55	56	0	2	5.3	5.0

C. ±4% interest-rate volatility

	New OAS		Chg in Price (ticks)		Eff. Dur	
	–4%	+4%	–4%	+4%	–4%	+4%
Collateral	13	–7	16	–19	6.4	6.0
QA (PAC)	26	26	0	0	1.7	1.7
QB (PAC)	50	45	3	–3	4.3	4.2
QC (PAC)	60	46	11	–14	6.5	6.2
QD (PAC)	65	47	18	–23	8.7	8.1
QE (PAC)	67	50	18	–26	10.9	10.2
HO (SUP PO)	473	552	–27	25	5.9	6.1
HZ (SUP)	70	37	26	–28	5.4	4.9

KEY POINTS

- Mortgage-backed securities are complex instruments. Traditional measures of valuation such as cash-flow yield and relative valuations such as yield spread or static spread are inadequate because of the prepayment option given to homeowners.
- The OAS valuation model is a sophisticated analytical tool available to assess value.
- The results of an OAS model should be stress-tested for modeling risk: alternative prepayment and interest rate volatility assumptions.
- OAS analysis helps the investors understand where the risks are in a CMO deal and to identify tranches that based on the model are fairly priced and those are possibly cheap or rich.
- Compared with a sophisticated analytical tool such as OAS analysis, traditional static analysis can lead to very different conclusions about the relative value of the tranches in a deal.

CHAPTER
FORTY-TWO

CONVERTIBLE SECURITIES: THEIR STRUCTURES, VALUATION, AND TRADING

MIHIR BHATTACHARYA, PH.D.
Managing Director
UBS Financial Services

Convertible debentures and convertible preferred shares, or more generally equity-linked securities, span the space from common stock on the one hand to nonconvertible (straight) debt on the other. While the majority of newly issued convertible securities combine a balance of the common stock and straight debt attributes, some are close proxies for common stock and others skewed toward straight debt. Some new issues may have maturity of as short as three years, as in the case of convertible notes and mandatorily convertible securities, while traditional convertible preferred shares are perpetual; that is, the issuer is not ever required to repay the par or the principal amount of the security. The vast majority, though, have maturity dates ranging from 5 to 30 years, with 5 to 10 years being the most common. Over time, a convertible security that may have started out as very close to straight debt may become very much like common stock due to price appreciation in the common stock into which it is convertible, called the *underlying stock*. The reverse is also true as the price of the underlying common stock declines.

Convertible securities have evolved significantly along with the market's sophistication in analytics, trading, and attention to risk. This chapter will examine the products that comprise the asset class, its evolution, motivations for their issuance and purchase, and their structural aspects. A substantial part of the chapter will focus on valuing these securities, colloquially known as *convertibles* or *converts*. Passing reference will be made to convertible markets in the other regions, namely, Europe, Japan, and non-Japan Asia.

The essential features of convertible products, and notable exceptions thereto, are as follows:

- A convertible security may be converted, generally at any time until its maturity date, into the underlying common stock. Exceptions: some converts may have an initial nonconversion period of 6 to 12 months, sometimes longer. Some may have a *Contingent Conversion* clause

whereby the conversion right of the investor only commences upon the underlying stock price exceeding a threshold price, usually ranging from 25% to 50% above the then effective conversion price, for a prespecified number of days.[1]

- The vast majority of convertibles are convertible into the shares of the issuer. The rest are convertible into shares of another publicly traded entity. These latter securities are called *exchangeables*.
- The conversion right rests with the investor. Exceptions: in mandatorily convertible securities, investors are not given a conversion option; they receive the applicable shares mandatorily at maturity. Some nonmandatorily convertibles may have a knock-in automatic conversion subject to the underlying stock price exceeding a threshold price for a prespecified number of days.
- Almost all converts have a redemption feature that allows the issuer to redeem them prior to maturity. Exceptions: some traditional convertibles and most mandatorily convertibles are nonredeemable.
- Even if convertible at any time, investors are likely to exercise the conversion right only in response to a redemption notice by the issuer—also known as the *issuer redemption* or *issuer call,* or simply, the *call.* In other words, virtually all conversions occur only when forced by the issuer. Exceptions: (a) when the underlying stock pays a high dividend and is also illiquid, e.g., Real Estate Investment Trust Stocks; (b) in the presence of material market friction such as future restrictions on conversion or it is costly to borrow the underlying stock to sell it short as a hedge; and (c) when the underlying stock price is above the *critical stock price,* discussed in further detail below.
- Upon conversion, the issuer will usually satisfy its obligation by transferring to the investor the specified number of shares of the underlying stock per convertible. This is called a *physical settle.* Exception: Sometimes the issuer may have the right, specified in the prospectus for the convertible, to satisfy its obligation by paying the investor the cash value of the underlying securities. This is known as the *cash settle option.* Depending on the liquidity of the underlying stock, a cash-settled convert may fetch a slightly lower price than would a physical settled convert due to the cost incurred by arbitrage and hedge fund investors in covering their stock short position. With some

1. Investors are unlikely to exercise their conversion option prematurely, as doing so would extinguish the time value of the conversion option embedded in the security. Despite this, if the convertible security structure allows the issuer the option to settle the conversion in cash, in full, or in part, the total liability of the convertible issue is deemed a short-term liability. The initial nonconversion period avoids this undesired detriment to the issuer's current assets to current liability ratio.

exceptions for deep-out-of-the-money convertibles, hedge funds short the underlying stock against a long position in the convert. In some instances, conversion is specified into a combination of the underlying stock and cash, or a specified combination of stocks or a choice among specified multiple stocks. The last case is called a *rainbow conversion option,* wherein the investor has the option of converting into that stock among the choices provided that results in the highest value upon conversion.

- A convertible's current yield or yield to maturity or yield to first put usually exceeds the dividend yield of the underlying stock.
- The price of a convertible is at least equal to the value of the shares into which it is convertible, that is, its *conversion value*. In other words, a convertible should trade at a non-negative premium to its conversion value. Exceptions may occur under the following conditions: (a) when there are restrictions on the investors' conversion right; (b) when the underlying stock is illiquid and the cost of borrowing the stock is high; (c) in anticipation of forced conversion leading to a loss of the accrued coupon—this feature is colloquially known as the *screw clause*—a currently redeemable, deep in-the-money, convertible may trade at a discount to its conversion value; and (d) in the case of cash settled convertible, which may cause additional transaction costs for arbitrage and hedge fund investors.
- Convertible debentures are most commonly issued as subordinated debentures, although senior subordinated and senior unsubordinated debentures are increasingly more frequent. Unsubordinated convertible debentures are generally the rule in Europe. When issued as either subordinated convertible debenture or convertible preferred, they are accompanied with relatively fewer restrictive covenants.
- Convertibles have a prespecified maturity. Exceptions include: (a) A handful of mandatorily convertibles whose maturities may be extended by a year at the option of the issuer; and (b) the "PHONES" convertible product (described below), in which maturity may be extended by as long as 30 years.
- Convertibles have a prespecified number of shares per convertible, i.e., a fixed *conversion ratio*. Exceptions: (a) The number of shares received upon conversion of a mandatorily convertible security is not fixed, but is a function of the underlying share price on the settlement date. However, the number of shares to be received is bounded by prespecified maximum and minimum limits; and (b) some Japanese and non-Japan Asian converts have a *reset* or *refix* clause whereby the conversion ratio is adjusted upwards, and the conversion price adjusted downward if the underlying stock price does not exceed prespecified trigger prices.

Evolving sophistication of convertible issuers, investment bankers, and investors has changed the convertible market in several key ways. Higher interest rate volatility has highlighted *duration risk* and *convexity* inherent in any security with a fixed income component, including converts. The increased volatility of corporate spreads (over U.S. Treasury or LIBOR or other interest rate benchmarks) resulting from concerns about corporate defaults as well as defaults by countries—the *sovereign defaults*—has heightened investor sensitivity to default risk. The consequent emergence and importance of *credit default swap* (CDS) as an instrument for risk transference for corporate and sovereign issues can hardly be overemphasized.[2] The volatility in corporate spreads, in the context of converts, raises concern regarding the reliability of a convert's estimated *fixed income floor* or *bond value*. As a result, to arrive at a better estimate of the bond floor and hedge against the default probability of a convert, CDS pricing level applicable for the issue and its trading have very quickly become integral parts of convertible valuation and arbitrage.

Convertibles have equity and interest rate options, and occasionally, currency options, embedded in them. The value of these options is a function of, among others: (a) Equity volatility; (b) interest-rate volatility; (c) spread volatility; (d) default probability; and (e) recovery value in the event of default. Except in some simple situations in which options embedded in a convertible are separable and therefore can be valued using simple models in an additive mode, in the vast majority of cases the options interact with each other and are not separable. Investors should, therefore, be aware of the inherent danger of attempting to value the embedded options as if they were separable options.

The balance of this chapter describes the evolution in the convertible product including details of their various structures, their pay-off diagrams, reasons for investing in them. This is followed by the basic characteristics of convertible securities at their various stages, their valuation parameters, and valuation models. We close by discussing aspects of trading these securities.

2. A CDS transfers the default risk of the underlying *reference debt security* from a holder of the reference debt who buys the CDS to the CDS seller. The buyer makes a stipulated series of quarterly or semiannual premium payments to the CDS seller as consideration. These payments continue until the maturity of the CDS unless terminated earlier upon the occurrence of the default event. The CDS seller, usually a financial institution that wants to assume the credit exposure, agrees to pay a stipulated percent of the notional amount of the reference debt in the event of default and upon receipt of a *deliverable security* from the CDS buyer. Naked CDS purchases, i.e., without also holding or acquiring the underlying deliverable reference security is a directional credit bet that the credit of the reference security and/or its issuer will decline or default. Various sovereign governments in the Euro-zone and elsewhere have, with dubious merit, blamed credit shorts via CDS, either covered or naked, for the financial pressures on their economies and have even banned such trading for a period of time.

EVOLUTION IN THE CONVERTIBLE MARKETS

While most of the issues in the convertible market continue to be noninvestment grade rating or are unrated, it is no longer true that only firms of marginal credit quality and/or firms unable to access public debt markets raise funds by issuing convertibles. This asset class has evolved into a sizable and mature one wherein issuers have raised large amounts, exceeding $1 billion each, some even through overnight transactions with very little marketing effort.[3] To understand this evolution and its future direction, it will be useful to segment this asset class into its distinct distribution channels.

Convertible Market Segments

The principal segment comprises of the publicly issued convertibles that includes those issued either as registered under the Securities Act of 1933 ("SEC registered") or under Rule 144A institutional private placement ("144A issue"). Gross proceeds at issue in this segment are of least $50 million each. Smaller size issues—generally from "small cap" and "micro cap" issuers—may not attract institutional buying interest and as a result tend to be illiquid with wide bid/offer spreads.[4] The present chapter will, therefore, focus on the publicly traded convertibles, though the economic and valuation logic apply to other convertibles as well.

Another segment of the convertible market consists of highly structured and individually negotiated transactions, wherein the issuer and a single investor or handful of investors draw up the terms and conditions of the investment and the structure of the convertible security purchased. This "private investment" is not available to investors at large. The specific one-off nonmarket features and covenants of privately placed issues may include: (a) a relatively high conversion premium in exchange for a high coupon or preferred dividend; (b) an extended period of nonconversion; (c) conversion into restricted stock which cannot immediately be monetized upon conversion; (d) a resetting of the conversion premium and/or coupon or preferred dividend based on balance sheet/income statement/cash-flow target ratios for

3. An example of a large issue is KfW Bank's Aaa rated €5.0 billion (US$5.66 billion) 0.75% exchangeable debt maturing on 8/8/2008, issued in July 2003. Microsoft Corporation's $1.25 billion 0% capped call maturing on 6/15/13, issued in June 2010, was also rated Aaa. China Petro Chemical's step-up coupon convertible bond for Yuan 23 billion (US$3.5 billion) priced on February 2011 is another example, although the issue is unrated.

4. Although convertible bonds may be listed on the New York Stock Exchange (NYSE) or the American Stock Exchange (AMEX), they are most frequently traded in the Over-The-Counter (OTC) markets. As a result, the price levels reported in the press may not be representative of the current market price indications. SEC registered convertible preferreds usually trade on the NYSE and AMEX. 144A convertible preferreds trade on the OTC market until they are registered or are *seasoned,* at which time they are listed and trade on the NYSE or AMEX.

specific time periods[5]; (e) debt covenant restrictions; (f) seniority in the event of bankruptcy, merger, or acquisition; and (g) provisions for voting and control issues. Typical investors are leveraged buyout funds, private equity funds, hedge funds and, occasionally, mutual funds. These buyers provide strategic capital infusion to distressed firms, firms needing added capital to restructure or grow through acquisitions, and firms not otherwise ready for, or unwilling to pursue, public market transactions. This set of investors tends to have medium or long holding period horizons, and have bullish projections about the future stock market performance of the firm and/or hedge themselves. Consequently, the lack of secondary market liquidity of the privately placed structured convertible is less of a concern.

Convertible Products Range

Convertible products[6] may be divided into three categories, based on their seniority in the balance sheet and the tax treatment of the preferred dividend. These categories are (1) convertible debt products; (2) convertible preferred products of the mandatory and the nonmandatory types; (3) hybrid products which are preferred shares from a financial reporting perspective, but are structured so as to be tax deductible, and thus to reduce the net cost to the issuer; and (4) structured public convertibles.

Convertible Debt Products

Convertible Debt Products' interest payment obligation can be in the form of cash coupons or interest accrual or both or neither. The "neither" case occurs when the value of the equity option embedded in the convertible offsets the value of coupon payments of an otherwise identical nonconvertible debt of the same issuer. Not surprisingly, the zero coupon nonaccreting structures are more common in low interest rate environments. Coupon payments and accrued interest are tax deductible and the issuer is accorded no equity credit from the rating agencies.[7] The products in this category include:

5. In the "post-Internet bubble crash," the reset feature of such securities has been criticized and often referred to as "death spiral" or "toxic." However, at the time of issuance issuers often either did not realize the extreme dilutive impact of this feature, specifically the continuing pressure on the stock price due to shorting by the investors to hedge their exposure to the stock, or did not consider it material, given their then expectations of stock price growth. Such toxic converts have fallen out of favor.
6. For the balance of this chapter, unless otherwise noted, we will use the term *convertible* for exchangeables as well. As may be expected, exchangeables are used to monetize stakes that an entity, be it a firm or an individual, owns in the shares of another publicly traded common stock.
7. Equity credit from rating agencies is outside the scope of this chapter. Suffice it to say that rating agencies have repeatedly indicated that with the exception of common shares, which (by definition) are accorded 100% equity credit, they do not adhere to a formulaic approach to assigning ratings for securities or corporate issuers. Nonetheless, one of the rating agencies has indicated the general range of equity credit that may be expected for a list of financial instruments. See Libby Bruch, "Integration of Rating Scales and Re-evaluation of Equity Credit," *Standard & Poor's CreditWeek,* February 24, 1999, pp. 9–11.

- *Traditional Convertible Debt:* Typical maturities are five, seven, or 10 years, with a 15% to 40% conversion premium, and a nonredemption period (*hard noncall*) of three years or longer. The bond is issued at par, matures at par, and has a fixed conversion ratio[8] and hence a fixed conversion price during its life. Basic variations include a higher conversion premium with a higher associated coupon, or a stock price trigger based conditional redemption (also known as a *provisional call* or a *soft call protection*).[9] The combination of an initial period of hard noncall followed by a soft call is often used to trade off against a lower coupon and/or a higher conversion premium. As a rule, the greater the volatility of the underlying stock and the higher its growth expectations, the greater the variation from the basic structure.[10] Reset or refix clauses are included when the outlooks for the firm or for the firm's primary economic domicile country, or both, are unfavorable. The conversion price is revised downward if some stock price triggers are not met. The reset clause lowers the risk to the investor and transfers it to the issuer.[11]
- *Zero-Coupon Convertible Debt:* Also known as LYON,[12] this product is a zero coupon, putable, redeemable, convertible debenture with 15 to 30 years maturity; with one day puts at accreted value at 5, 10, 15 years

8. Conversion ratios for all converts are adjusted for stock splits and special situations, such as special dividends or distributions, as specified in the prospectus for each convert. They may also be adjusted for increase of regular dividends beyond a prespecified dividend payment rate per share threshold.
9. A "two-year hard plus one year 130% soft" means that the convert is not redeemable in the first two years from issue date. It is conditionally redeemable in the third year only if the stock price is at least 30% above the conversion price for at least twenty out of thirty consecutive trading days; after the third year, the convert is redeemable unconditionally. Provisional triggers usually range from 120% to 150%.
10. For example, Amazon.com issued a $1.25 billion, 10-year maturity convertible debt with a coupon of 4.75%, and conversion premium of 27%. Amazon.com is a very volatile stock with strong name recognition as a market leader in the internet retail sector. It was able to issue the convert after a one-day marketing and increase the issue size from an initially announced $500 million to a finally executed $1.25 billion based on investor demand. The structure provided no hard call protection. Instead, it had a three-year "150% provisional redemption with investment *premium makewhole.*" This means that if the 150% trigger condition were satisfied during the first three years, then the issuer may force conversion. However, the issuer would then simultaneously have to pay the investor a cash amount of $212.60 [= $1,000.00 less ($1,000.00 divided by 1.27)] per bond. The net effect upon conversion is as if the investor purchased Amazon.com common stock on the date of issue of the convert. A more common variation currently is the *coupon makewhole* as distinct from the premium makewhole. In this variation, if redeemed during the makewhole period, the issuer pays the arithmetic dollar difference between the stipulated coupon stream until the noncall date minus coupons already paid prior to the redemption date.
11. The reset structure was developed in Japan during the 1990s when its economic growth was anemic at best. There is an element of the "death spiral" element here. However, with a downward reset limit feature usually included in the structure, say, conversion price declining to no less than 50% of the initial conversion price, a total death spiral is avoided.
12. Liquid Yield Option Note is a service mark of Bank of America Merrill Lynch.

from the settlement date following new issuance; and with a hard noncall until the first put date. Thereafter, the issue is unconditionally redeemable at any time at the accreted value. The debenture is issued at a discount to par, calculated at the semiannually compounded yield to maturity of the security. For example, a 5% yield to maturity, 20-year LYON will be issued at a price of 37.243% of par, which is the present value of $100 discounted at 2.5% for 40 periods. The initial conversion premium ranges in most cases from 15% to 40%. The conversion ratio established at issue remains constant during the life of the security. As a result, since the bond value is accreting toward par while the conversion ratio is fixed, the conversion price rises continuously.[13] Attractive features of this security from the perspective of the issuer include:

- Conservation of cash and the option to deploy it at the (presumably higher) internal rate of return of the issuer;
- Tax deduction on the accrued interest;
- Upon conversion, the per bond equity addition to the balance sheet is comprised of the initial issue price plus the accrued interest amount;
- Upon conversion, there is no re-capture (by the Treasury) of the accrued tax deduction;
- The LYON and its zero coupon variation of the CoCo structure (discussed later) are, all else being equal, the most debtlike of all equity-linked securities with the highest effective conversion price;
- This structure signals to the market that the issuer is unwilling to sell equity at the spot price at issue but only at the high effective conversion price.

The trade-offs to investors for the rising conversion price include the higher option value in the five years of hard noncall; a higher accretion rate; and the option to put the security back to the issuer at accreted value at the stated intervals.[14] Among the typical variations in the structure are higher conversion premiums for highly rated issuers and/or high volatility–high expected growth stocks, sometimes in conjunction with a first put in year 3 with a corresponding hard noncall also for 3 years.

13. Continuing with the numerical illustration, assuming that the stock price of the underlying share to be $45.00 per share, and the initial conversion premium of 25%, the initial conversion price is = $45.00 × 1.25 = $56.25 per share. The conversion ratio per bond accreting at 5% and 20 year maturity will be the issue price divided by the initial conversion price = (372.43/56.25) = 6.621 shares. In five years, the bond will accrete to $476.74, which is the issue price compounded at 2.5% for 10 semiannual periods. The effective conversion price will then be = (476.74/6.621 shares) = $72.00 per share. In options terminology, these bonds have strike prices increasing with time.
14. The puts are sequential European puts, also known as *Bermudan puts*; they can be either *hard puts* or *soft puts*. In the former, upon exercise of the put, the investor is paid the put amount in cash. In the latter, it can be satisfied in cash or shares equal to the value of the put amount, or combination, at the option of the issuer. Earlier versions had an equal value of a new straight debt security as a third alternative; this alternative has been dropped due to ambiguities regarding the valuation of the new debt security.

Other variations include longer first put date, often in year 7, as well as nonsymmetric put and call dates with the first call date occurring before the first put date.

- *Original Issue Discount Convertible Debt:* This structure (called the *OID convert*) combines aspects of the preceding two structures in that a small part of the yield to maturity is paid in the form of cash coupon, and the balance accretes. As is to be expected, all else being equal, the yield to maturity in this structure straddles those of the preceding two structures. The conversion price is also rising but at a rate lower than that for the zero coupon structure. Maturity for this product is usually five to seven years with a typical hard noncall protection of three years and is typically not putable prior to maturity although there is no reason why it cannot be structured with, say, a put in year 3 and final maturity in year 5 or 7.
- *Premium Redemption Convertible Debt:* This is simply another variation of the OID convert. The only difference between this variation and the OID is that the latter is issued at below par and accretes to par at maturity, while the Premium Redemption Convertible is issued at par and accretes in exactly the same manner to a number above par and hence the name. This structure occurs more in Europe and Asia, where regulations may require the issuance of bonds at par.
- *Step-Up Convertible Debt:* This product follows a *pay-in-kind* or *PIK* structure common in the non-investment-grade debt market, wherein the security pays no coupon for a period of up to five years. The coupon then steps up to a higher level cash coupon than what it would have been if it were current coupon paying from the start. Adapted for the convertible market, this security pays a low cash coupon for the first three years, which is also the hard noncall period. The coupon then steps up for the balance of the life of the convert that ranges from another four to seven years. The effective conversion price rises continuously until the last low-coupon payment date, and stays constant at its higher level thereafter until maturity. As might be expected, the absolute levels of the coupons in step-up convertibles are much lower than those in the high-yield market due to the inclusion of the conversion option. Interest is expensed at the rate of the yield to maturity, which is higher than the cash coupon during the low coupon period, but lower than the cash coupon rate in the later period. The incentive for the issuer to redeem this security prior to the higher coupon kicking in is therefore very strong. A flip-side variation of the structure, particularly in low interest rate environments, is the step-down convertible wherein after an initial cash coupon period the coupon drops to a lower level or to zero with or without accretion.

Contingent Convertible Bonds

In most convertibles the investor has an American option to convert into the underlying stock. As a result, Generally Accepted Accounting Principles (GAAP) require that the denominator in the earnings per share (eps) calculation add the new number

of shares to be issued upon conversion of this convertible to the existing number of shares outstanding. The increase in the number of shares in the denominator—and hence eps dilution—occurs immediately upon the settlement of the newly issued convertible transaction and is based on the conservative assumption of immediate conversion by the investor. In this nicknamed *CoCo convertible,* the conversion option granted investors is not immediate but contingent upon the stock price exceeding a prespecified hurdle, i.e., the investor's option to convert "knocks in." By adopting this twist, first introduced in 1999, the issuer did not have to recognize immediate eps dilution but could defer it to the knock-in date. Under those rules, the CoCo structure grew to dominate U.S. convertible new issuance. The majority of the issues were investment grade, and the transactions generally very large, as the non-immediate dilution feature was particularly attractive to issuers.

However, that was before the Financial Accounting Standards Board's Staff Position APB 14-1 in May 2008 and adopted shortly thereafter. It established that prospectively as well as retroactively, all convertible debt would be treated under the "bifurcation concept," i.e., viewed as a combination of straight debt plus an equity component. Consequently, regardless of the CoCo structure, eps dilution would be recognized immediately upon issuance of the convertible security. As a result, the issuance of CoCo convertibles has declined materially from its peak. CoCos now may, at the option of the issuer, settle in shares, i.e., physical shares settlement, or a combination wherein the par value may be paid in cash and the in-the-money component paid in shares, called *net share settlement,* or both components paid in cash. Clearly, the latter two alternatives are aimed at reducing the number of shares delivered upon conversion.[15,16,17]

---

15. Assume that at settlement the stock is at $45, the conversion ratio for the bond is 32. Then the intrinsic value of the bond is 45 × 32 = $1,440. Under the net share settlement, the investor receives $1,000 cash toward the par value and 440/45 = 9.7778 shares.
16. A brief note regarding the bifurcation principle: Under the *debt method,* a $1,000 par convertible would be viewed as, say, $850 of discounted debt that will accrete to $1,000 at maturity, and the $150 equity component to be accounted as equity. The interest expense would be increasing over time to maturity and is computed as the accreted bond liability times the straight, nonconvertible debt rate applicable to the bond at the time of issuance of the convertible security. Note that under the old method the debt expense would have been par times the cash coupon of the convertible which would have been lower that the nonconvertible bond rate. The increased interest expense flows through to the earnings calculation. Upon conversion, the eps is the more dilutive of (a) the debt method above, or (b) the fully diluted "equity method" in which all the shares underlying the bond are included in the denominator, not just the shares paid out in the net share settlement method.
17. Lately, following the financial turmoil of 2007/2008, the term "CoCo bonds" has been applied in a totally different context. These CoCo bonds, issued by banks and financial institutions, may be converted into equity at the option of the issuer banks if/when their business losses cause their core capital ratios to decline below regulator-mandated levels. The bond investors, in effect, have sold an embedded credit put to the issuing financial institutions and, therefore, have no say if and when this variety of CoCo bonds will be converted into equity to the detriment of the investor. Very unlike the CoCo bonds discussed here it is more like a *reverse convertible,* wherein, once again, there is an embedded put sold by the investor to the issuer. Not surprisingly, neither of these issuer putable securities is traded on the convertible desk.

- *Contingent Payable Bonds:* As one might surmise from the name, these *CoPay* bonds knock-in contingent payment by the issuer to the investor subject to the stock price exceeding a pre-established threshold. The Co-Pay feature generally helps defer voluntary conversion by the investor thereby allowing the issuer to continue claiming interest deduction on a typical long-dated structure since the bifurcation method also applies here. Conditioned on a credible probability of the contingent payment, the issuer can deduct interest expense at the long term straight debt rate matching the maturity of the security. The magnitude of the tax benefits of this structure varies depending on whether the security is ultimately converted or not, but in either case it potentially generates significant tax benefits to the issuer. The Co-Pay structure may also be embedded inside CoCo or any of the accreting structures.
- *Negative Yield Convertible Debt:* Yield on the benchmark 10-year Yen denominated Japanese government debt has hovered below 1% for several years and was at 0.54% as of 3/10/11 for five-year Japanese government bonds (JGBs). Dividend yields on Japanese equity are traditionally very low. Under this scenario, consider a yen denominated, zero coupon, low conversion premium, unsubordinated convertible debt with an effective maturity of five years issued with hard noncall also of five years. Its theoretical value would most likely be a few points above par. To make it equitable to both issuer and investor, such a convert might be issued at 1% to 3% above par, yet it matures at par thereby resulting in a negative yield to maturity security. Not surprisingly, this structure will be more frequently used in a low interest-rate environment and particularly so when combined with high volatility in the underlying stock.

Increasingly, convertibles debentures have been issued as senior unsubordinated debt, pari passu with senior existing or future nonconvertible debt of the issuer. This feature has long been common in convertible bonds issued out of Europe and is particularly suited for CoCo/CoPay structures. The collateral benefits accruing from of this structure are the increased liquidity due to it facilitating capital structure arbitrage trading as well as credit hedging via CDSs in addition to a higher tax deduction rate.

Convertible Preferred Products

Convertible preferred products are senior only to the issuer's common stock. The preferred dividend is not tax deductible, and hence is a costly source of funding on an eps basis. Convertible preferreds are mostly issued, therefore, when the firm needs equity credit from the rating agencies, or when it is unable or unwilling to issue debt due to leverage covenants imposed on them by other classes of senior securities, or when the firm does not pay taxes due to accumulated losses or a combination of these reasons. These products are viewed as "permanent" or long-term financing and provide the issuer with the option to skip payment of preferred

dividends without triggering default. Hence they are generally accorded up to 50% equity credit from the rating agencies.[18,19] Withholding taxes and the low bond floor equivalent resulting from the perpetual maturity are the primary reasons why these structures are not commonly issued in Europe. Withholding tax on preferred dividends applicable to non-U.S. investors deters them from investing in U.S. preferreds too. The products in this category may be further subdivided into those that redeem at par if not converted, that is, without impairment to the original investment, and those that convert mandatorily into a formula number of common shares at maturity. In the latter case, investors may lose part of their initial investment if the stock price falls below that on the date of issue.

Nonmandatorily convertible preferred shares include:

- *Perpetual Maturity Convertible Preferred Shares:* This is the preferred share counterpart of the Traditional Convertible Debt described above in that it has a fixed conversion price, it is a very easy structure to understand, and has been a staple of the convertible market for several decades. The main differences are its perpetual maturity and lower seniority. Consequently, the dividend on the convertible preferred will be higher than the coupon on an otherwise identical convertible debt. The higher rate on the preferred results from the fact that both the corresponding benchmark interest rate and the credit-spread corresponding to this longer maturity are higher, and the two together form the base rate.[20] The dividend rate on the convertible preferred is determined by adjusting downward from this higher base rate for the embedded equity option.[21,22]

18. While skipping preferred dividends does not result in default, it does tend to severely depress the stock price. Restrictions on common dividend payments, board seats to preferred shareholders and other remedies may be imposed on the firm until the arrears in preferred dividends are paid. Consequently, the option to skip preferred dividends, although embedded in the structure, is resorted to only when the firm is in financial distress.
19. Issuance of traditional preferred shares, in most cases, is viewed as helping prevent a ratings downgrade but not necessarily help in a ratings upgrade. Since mandatorily convertible securities, by structure, are certain to convert into common shares within three years and at most in five years, they are viewed more akin to common shares, and therefore may be accorded up to 85% equity credit. This applies to all flavors of mandatorily convertible securities—preferred, exchangeable debt, or hybrid tax deductible preferred.
20. When the 30-year Treasury bond was the longest dated liquid benchmark, preferred were priced off of its yield to maturity. However, since 2001 when the Treasury halted regular issuance of the 30-year bonds—although it has been brought back with limited frequency and liquidity since 2006—the 10-year U.S. tenor is the most liquid long-dated U.S. Treasury security, converts are priced off of this benchmark. The CDSs are also typically 5-year tenor and occasionally longer.
21. This logic applies to all converts.
22. A variation of this security allows the issuer the option to exchange the convertible preferred for an otherwise identical convertible subordinated debenture of maturity 10 years from the original date of issue. Issuer will usually exercise this option when it returns to tax-paying status.

- *Dated Convertible Preferred:* Again a convertible adaptation from the high-yield market, this product has a maturity of 10 to 12 years, although 30-year dated convertibles have also been issued. Typically, it matches or is outside the maturity of high-yield debt which is usually 10 and sometimes 12 years. If not converted, a dated convertible preferred must be redeemed at par at maturity. In all other aspects it is similar to the perpetual maturity convertible preferred. Rating agencies are less likely to accord any equity credit due to this product's debtlike redemption at maturity feature and is almost always used by noninvestment grade issuers faced with covenant restriction limits.
- *Step-Up Convertible Preferred:* This product is analogous to the step-up convertible debt, but with perpetual maturity.

Mandatorily convertible preferred shares in essence transfer the downside risk of the stock to the investor in exchange for a higher preferred dividend. This category of converts includes:

- *Capped Common:* Also known as PERCS,[23] the capped common is essentially a combination of purchasing a common share and writing an out-of-the-money call to the issuer. Investors have no conversion option at any time during the life of the security, which is typically three years and sometimes shorter. The issuer, however, may redeem this convertible at any time provided the preferred dividend due until the maturity date is paid in its entirety. The premium for the call option that the investor is short is packaged in the form of quarterly preferred dividends. This packaging of a common options strategy, known as the *buy-write* strategy, allows convertible funds to invest in them. Were these three-year convertible securities unbundled, the charter of convertible funds which may disallow pure play option positions would generally prohibit such investment. The investor in the capped common realizes all of the stock price appreciation from the spot price at issue up to the cap or strike price level; anything beyond the cap price is retained by the issuer. On the other hand, the investor loses part of her principal to the extent that the stock price at maturity is lower than the price at issue. In a rising equity market, the issuer has almost always exercised the call option and this product has under-performed the common stock from an investor perspective. Consequently, its popularity has declined considerably. Rating agencies may generally be expected to accord equity credit of up to 85%.

23. The Preferred Equity Redemption Cumulative Stock (PERCS) is a service mark of Morgan Stanley.

- *Modified Capped Common:* A variation on the above, the modified capped common may be viewed as a PERC with some downside protection to the investor, in the form of an embedded put the investor purchases from the issuer. Microsoft Corporation was the first to use this structure in 1996; it offered $1 billion of this security with a cap of 28% on the upside, but without any downside risk to the investor; that is, with no hit to the principal. The embedded put purchased by the investor for this three-year maturity security was an at-the-money European put on what was then a high volatility stock, and hence was very expensive. The net option premium paid to the investor in the form of preferred dividend was accordingly low.[24]
- *Mandatorily Convertible Preferred:* This structure, invented in 1993, and its hybrid version, the *Trust Mandatory Preferred* (described below) have been so frequently used to raise funds in the convertible market that it has spawned a host of acronyms.[25] Typically, it is issued at the same price as the underlying stock price; matures in three to five years, most frequently three-year maturity. It has a conversion premium in the 20% to 22% range, but may be higher in low interest rate regimes. It is easiest to view this security (popularly known as a *mandatory*) as a traditional convertible with a three-year maturity that is share settled, packaged with an embedded at-the-money put purchased by the issuer from the investor. The number of shares received by the investor at maturity depends on the share price on the maturity date.[26] This security's popularity has stemmed from the high equity credit from rating agencies, the transfer of risk to the investor in the event of a decline in the share price, and the traditional convertible features on the upside. Because the issue is settled in shares, the question of credit risk of the issuer with respect to payment of par is irrelevant. Only the credit risk with respect to the payment of the preferred dividends remains. Consequently, the structure is relatively insensitive to the creditworthiness of the issuer. The typical high preferred dividend rate of the mandatory being attractive to the buyers is another reason for its popularity.

24. Microsoft Corp. Series A 2.75 % Convertible Preferred issued on 12/17/96 maturing on 12/15/99; cap at 28%.
25. The service marked acronyms, followed in parenthesis by their respective investment banks, include: DECS (Citigroup), PRIDES (Bank of America Merrill Lynch), ACES (Goldman Sachs), PEPS (Morgan Stanley) and SAILS (Credit Suisse First Boston).
26. Assuming a spot stock price of $100 a share, the mandatory will also be issued at $100. If the conversion premium is 20%, the minimum conversion ratio is the issue price divided by the conversion price = $100.00/120.00 = 0.8333 shares per mandatory. If the stock price at maturity is at or above $120 the investor receives 0.8333 shares. If the stock price is at $100 or below, he receives one share that is the maximum number of shares per preferred. So, in the event that the stock price is $65 at maturity, the investor has a hit to the principal of $35 per share. If the stock price is between $100 and $120, the investor receives between 0.8333 and 1.0 shares so as to be worth the initial investment of $100. Sometimes for the sake of standardization, the par amount is set to $50 or $1,000; the conversion ratio is calculated in exactly the same way.

- A variation on the preceding structure, the *modified mandatory convertible preferred* provides the investor with downside protection for the first 10% to 25% from the spot price, in exchange for a lower preferred dividend. In effect, the net put component of the package purchased by the issuer is 10% to 25% out-of-the-money. Hence the put premium is lower, and this is translated as a lower preferred dividend. The maximum number of shares is 1.111 for a 10% out-of-the-money put case, rather than the one share in the at-the-money put case of the traditional mandatory. The equity credit accorded is identical.

Mandatorily and modified mandatorily exchangeable securities (wherein the underlying stock is different from the issuer's common stock) can be issued as debt securities whereas a mandatorily convertible security issued on the issuer's own stock is deemed as a forward sale of the common and hence is not tax deductible. Specialized structures, the specific details of which are outside the scope of this chapter, are crafted in compliance with the applicable tax code in order to achieve effective tax deductibility. The next subsection briefly outlines these hybrid products.

Hybrid Convertible Products

This category consists of structures which are treated as preferred shares for financial reporting purposes, but their distributions are tax deductible. The development of hybrid convertible preferreds closely followed the invention of the MIPS, QUIPS and TOPRS[27] in the fixed-rate nonconvertible preferred market. The essential structure in this category is as follows: a Trust[28] issues convertible preferred shares to investors and simultaneously uses the proceeds to purchase convertible subordinated debt from the issuer. The convertible subordinated debt will be the sole asset of the Trust. The coupon from the issuer to the Trust exactly mirrors the preferred dividend paid by the Trust. Upon conversion by the investors, the Trust in turn converts the convertible debentures and passes through the shares to the investors.

- *Trust nonmandatory preferred:* The maturity of this product ranges from 15 to 30 years and equals the life of the Trust; its cash distributions and maturity mirrors that of the convertible debenture purchased by the Trust from the issuer. Investors are generally not sensitive to the structural difference between these securities and the traditional perpetual convertible preferred. Rating agency equity credit may be equal to that of the traditional perpetual convertible preferred, although recent discussions might lead this product to be viewed as being closer to debt.

27. Monthly Income Preferred Shares (MIPS) and Quarterly Income Preferred Shares (QUIPS) are service marks of Goldman Sachs. Trust Originated Preferred Securities (TOPRS) is a service mark of Bank of America Merrill Lynch and is more descriptive of the structure.
28. The Trust qualifies as a closed end fund under the Investment Company Act of 1940.

- *Trust mandatory preferred and modified mandatory preferred:* This product is similar to its non-tax-deductible counterpart, except for the complexities involved with the Trust and the forward purchase contract between the investor and the issuer which is required to ensure mandatory conversion at the end of the life of the Trust, typically three years. Variations among the trust mandatory preferred relate to the structure and conditions regarding the forward purchase contract. Trust structure is also employed when the entity selling the shares is not an SEC registrant, but rather an individual or an investment or venture capital partnership. If the creditworthiness of the corporate issuer is less than acceptable, or the seller is not an SEC registrant, preferred dividends due the investors over the life of the security are escrowed in the Trust in the form of Treasury strips with maturities matching the scheduled preferred dividend payment dates. On the date of issue, proceeds from the sale of the Trust mandatory preferred to the investors, less the cost of the Treasury strips and Trust administration costs are forwarded to the issuer. The underlying shares are simultaneously escrowed in the Trust so as to create a bankruptcy remote Trust with an implied AAA credit rating.

Zero Premium Exchangeable Debt

This product acronym "PHONES"[29] is a 30-year zero conversion premium security issued at the same price as the underlying share into which it is exchangeable. It is redeemable by the issuer at any time, and convertible by the investor at any time, though there may be an initial nonconversion period. However, if the security were to be converted by the investor in the initial 30-year maturity period, the conversion ratio will be 0.95 implying a 5% penalty for voluntary conversion. The security is extendible for a further 30 years, subject to certain minimal conditions, at which time the conversion ratio becomes one share. The investor receives a pass-through of the dividend paid by the underlying share plus a fixed interest component. Any increase in the dividend paid by the share is deemed return of principal and deducted from the residual "par value" which is initially equal to the original issue price. Investors are liable for taxes on income deemed as received at the issuer's subordinated straight debt rate, which considerably exceeds the interest paid by the issuer. In exchange, the investor's basis for the share will rise with time. Zero premium exchangeable debt, at its most basic level, is a tax advantaged way for the issuer to monetize its holding of the underlying shares without actually transferring ownership of the shares. It thus potentially allows the issuer to defer the capital gains tax for as long as 60 years while enjoying a much larger interest deduction than cash coupon paid (6% imputed rate versus 1.75% actual cash coupon rate in one instance). Given the substantial tax advantage it provides

29. Participating Hybrid Option Note Exchangeable Securities (PHONES) is a service mark of Bank of America Merrill Lynch. Another investment bank calls it "ZONES."

the issuer it is attractive for the issuer. However, due to its material tax liability for a taxable investment entity, this product is most likely to appeal to tax sheltered investment vehicles of the equity income type, tax sheltered index funds, and off-shore hedge funds. Many investors do not consider this security to be a convertible, as it lacks any meaningful convexity and their popularity has fallen off.

Structured Public Convertibles

A recent innovation to reduce earnings per share dilution relating to the issuance of a convertible entails combining it with an equity derivative overlay transaction. The most common among these is the "call spread overlay." Consider a convertible issued with a 25% conversion premium. With part of the proceeds from the sale of this convertible the issuer buys from an investment bank an off-setting 25% out-of-the-money call matching exactly the conversion option embedded in the convertible in its maturity, number of shares and redemption features. Further, the issuer sells a 50% out-of-the-money call with identical features. In so doing, the issuer has reduced the potential dilution impact of the convertible through this net 50% out-of-the-money call. In addition, the net cost of the call spread can be deducted for tax purposes. Furthermore, the investment bank, as the seller of the call spread, has to hedge itself—in the 25% to 50% out-of-the-money range—by buying the underlying shares, thereby benefitting the stock. At maturity settlement for the investor in the convertible is as usual and can be in shares or cash or combination. If the stock exceeds the 50% threshold, the settlement with the investment bank is in net shares.

Exhibit 42–1 provides a schematic of the terminal payoff diagrams for the major convertible securities. Similar payoff diagrams can be drawn for the other convertible products.

Since the upheaval in the convertible market in 2005, and even more dramatically in 2007–2008, issuers and investors have moved noticeably to the simpler product structures. Traditional convertible bonds, mandatories, and convertible preferred shares have been chosen over some of the more complicated structures described above.

Investing in Convertible Securities

The most frequently cited reason to invest in convertibles is that convertibles provide upside participation with downside protection. While generally true, it does not fully apply to mandatory securities in which the investor retains the downside risk of the stock. Since convertibles span the space between equities and straight debt, the risk profile of each convertible product contains elements of both. Investors will choose from the subset of convertible offerings that match their target risk-reward profile and/or their assessments of the future levels of the underlying stock price, interest rate and credit-spread levels, volatility parameters, as well as market technicals such as supply/demand and liquidity. These are discussed in detail in the following.

EXHIBIT 42–1

Equity-Linked Payoff Diagram

Institutional investors in convertible securities can be broadly classified into *outright* investors and hedgers. Outright investors include the dedicated convertible funds, equity income funds, insurance companies, and fixed income funds seeking to participate in the potential upside in the equity. Convertible mutual funds, money managers who manage third party funds such as those from pension funds with specific allocation for convertibles as an asset class, as well as in-house managed funds earmarked for convertibles are also included in this category. The main hedge funds participants include those focused on convertible arbitrage, equity volatility arbitrage, and capital structure arbitrage. The common investment objective of the outright investors is to obtain equity exposure with portfolio volatility lower than that of common stocks. They are active money managers and are often measured by holding period returns compared to benchmark indexes such as the Standard & Poor's 500 Index, or the Russell 2000 Index of small stocks, or a risk adjusted benchmark. A subset of managers is measured by the Sharpe ratio.[30] An aspect of the charter of outright convertible funds is that they may not be allowed to hold the common shares received upon conversion nor permitted to hedge their convertible positions. That flexibility is left to the convertible arbitrage funds.

30. Sharpe ratio is defined as the excess return of the portfolio divided by the risk of the portfolio as measured by the standard deviation of its returns. Portfolio excess return is the realized return of the portfolio minus the return from the riskless asset. It attempts to measure the excess return per unit of risk undertaken by the portfolio manager. The measure can be applied to portfolios or to asset classes. The higher the Sharpe ratio, the better is the performance of the portfolio manager or the asset class.

The assets under management dedicated to convertibles, particularly by hedge funds, in the past decade has dramatically altered not only the size of this asset class, but also the way convertibles structured, marketed, evaluated, and traded. Convertible hedge funds went from being a significant part of convertible market to being the most dominant segment leading up to 2007 when they were variously rumored to be more than 80% of the funds invested in U.S. and global convertible markets. Further, due to their high portfolio turnover, they accounted for the majority of the liquidity provided. The financial illiquidity of 2007–2008 hit dedicated convertible arbitrage funds very hard forcing many to shut down while multistrategy hedge funds drastically reduced their allocation to the strategy. As they ceased to be the buyers to drive the new issue pricing, outright buyers with a longer holding period horizon have seen new issue pricing move in their direction and now account for a larger segment for the asset class than before the illiquidity event.

Outright investors will seldom buy a convert unless they like the fundamentals, or the *equity story,* of the underlying stock. Ideal attributes of an issuer, from outright investors' perspective, include

- A strong management team with a well articulated business model
- Presence in a growing sector of the economy
- The firm being in the growth phase of its business cycle
- Strong or improving credit with the ability to undertake the fixed liability without jeopardizing its credit rating
- Credit-spread established by an actively traded nonconvertible bond by the issuer or indications of credit default swap or asset swap levels
- High volatility stock
- Little or no dividend on the common stock
- Liquid secondary market for the convertible and the underlying stock

Additional items considered by hedge funds, who are essentially relative value investors, include:

- Cost to borrow the stock
- Richness or cheapness of the implied volatility of the options embedded in the convertible versus those of comparable listed equity options and the historical volatility of the underlying stock. This forms the basis of volatility trading.
- Implied equity volatility of credit default swaps and *equity default swaps*. Together with implied volatility of comparable equity options.
- Credit-spreads for all levels of seniority of obligations of the underlying stock, including the convertible with a view to *capital structure arbitrage*. The idea is to arbitrage (a) credit-spread mispricings, (b) differential implied probabilities of corporate default, or (c) recovery rate in the event of default embedded in the pricing of these obligations.

Thus, evaluating a convertible encompasses, among others, fundamental equity research, analysis of interest rates, credit-spreads, capital structure, associated equity and debt derivatives as instruments of trade expression or hedging, market technicals, liquidity of the security itself as well as the restriction on, and costs of, shorting the underlying stock. To understand the arena where this increasingly sophisticated analysis is deployed, we discuss convertible new issues next.

Convertible New Issues

Publicly issued convertible new issue product in the United States has had its ups and downs as it grew steadily in size from $12 billion in 1992 to over $106 billion in 2001 before the collapse of the dot.com boom and did not recover to the $100 billion level until 2007. And, not surprisingly, it dropped off again following the global illiquidity crunch that followed, ending with a paltry new supply of $39 billion in 2010. Taking the maturing issues into consideration, there was indeed a net contraction of the market during these years. Globally, the new issuance peaks and valleys roughly mirrored the United States' pattern with total issuance of $180 billion in 2003, $198 billion in 2007, and ending with $101 billion in 2010. While geographically continuing to be the most liquid of the convertible markets with the largest new issue calendar, the United States' proportion of the global new issues has fluctuated from as high as 61% in the challenged market conditions of 2008 to as low as 38% in both 2009 and 2010, but accounted for more than half of global issuance for most years in the last two decades. European issuance, on the other hand, has been steady at mid-teen to mid-twenties percent, with a spike to 37% in 2009. Japanese issuance in the current century ranges in the mid-single-digits to a rare spike of 16% in 2004—due to a few large transactions including one by Toshiba Corp for Yen 100 billion (US$923 million)—and considerably below the levels of issuance commensurate with its prior decades of growth. However, as might be expected, the portion of non-Japan Asia new issuance—at 25% in 2010—is considerably higher in keeping with their very high rates of growth compared to those of the developed regions comprising the United States, Western Europe, and Japan.

What determines the amount and type of convertible financing selected by issuers? One key factor, surely, is the economic cycle, along with the equity and bond market environments. As might be expected, in the low interest environments, issuers will clearly prefer to build up their capital base/extend maturities/restructure their balance sheets by issuing straight debt rather than dilute their earnings by issuing equity or equity-linked securities. Banks and financial companies, particularly, and others that bore a major brunt of the downturn were the exceptions with mandatories being the structures of choice for them. Hence the structure of convertible financing has a cyclical element to it with tax and accounting rules as factors being not far behind. Governmental financial inputs to stabilize global economies and the resultant or concurrent low interest rate environment are

expected to curtail convertible new issuance until the economies are in stronger recovery stages. History provides an indication of the choice of structures.[31]

Despite the lull in convertible new issues since the 2007–2008 financial crisis years, 15 converts were issued in the United States with proceeds exceeding $1 billion each, from 2009 on to the first quarter of 2011. Select examples are: (a) 4.75% mandatory maturing on December 1, 2013, issued by General Motors on November 18, 2010, as it emerged from bankruptcy; (b) Citigroup's 7.5% mandatory maturing on December 15, 2012 and issued on December 6, 2009 for $3.5 billion to add equity to its capital base; (c) Intel Corp.'s 3.25% convertible bond maturing on August 1, 2039 and issued on July 21, 2009 for $2.0 billion; and (d) MetLife Inc.'s $3.0 billion mandatory issued on March 3, 2011 and maturing on September 11, 2013, carries a preferred dividend of 5.0%. Depending on market conditions, the average size of a U.S. convertible issue has ranged from a low of $160 million to a very respectable and liquid $550 million. European issues are roughly comparable in size, although with larger variations from year to year, while non-Japan Asia issues are gradually increasing in size to an average of $225 million in 2010. While Japanese issues are predominantly Yen denominated and European issues in Euro, even in these countries US$ denominated issuance is not uncommon and is the currency of choice in most non-Japan Asian issuance.

When US 144A transactions started being issued with increasing frequency, they were not kindly received, as many tended to be overnight issues as opposed to being registered and fully marketed over a few days or weeks of road shows.[32] That is, the issues are announced after the trading day is over, orders solicited that same night or early the next morning, and the transaction completed before trading starts that morning. Over time, the ire over 144A issuance has tempered as investors have come to accept their inevitability. The demand for the product is largely unaffected while issuers do not need to provide investors a number of days, as is done in registered offerings, to study the details of the company's finances

31. As the economic conditions recovered in 1995 and peaked in mid 1998, the tax-deductible mandatory convertible and the tax-deductible nonmandatory convertible preferred increased in importance. Issuance of traditional convertible debt declined substantially in 1998 and came to a virtual halt following the Russian government bond default in mid-1998 and the Asian/emerging market contagion then in full swing. Convertible financing in the first half of 1999 was off significantly from that of the previous year, due to fears of rising interest rates but spurted in the last quarter of 1999 amid a recovery and start of the boom cycle. Convertible debt as a percent of total issuance jumped up to more than 80% in 2000 and 2001. With the burst of the Internet bubble, preferred share structures returned in favor at 42% of total gross proceeds in 2002. However, 2003 saw the resumption of the dominance of convertible debt issues, particularly the zero coupon/part coupon/CoCo structures, as interest rates continued to be extremely low in real terms. The CoCo bubble was burst by the FASB change cited earlier.

32. As an alternative to a US SEC registered offering which can be sold to any investor, including individual investors, 144A issues can be publicized, sold, or resold only to the larger institutional investors and Qualified Institutional Buyers (QIBs). This avenue, available to SEC registrant firms who are current with respect to filing financial reports with the SEC or those that agree to make the financial reports available to investors, allows new issue or secondary transactions to be executed without having to undergo the time-consuming registration process.

and/or the transactions prospectus thanks to a large extent to hedge funds, institutional buyers and QIB's as they can quickly respond to the new issue offer.

Although the total issuance volume in this asset class pales in comparison to both investment grade and high-yield issuance in the United States, they are still healthy. And in countries and regions in which the straight debt market is not as developed, convertibles are the vehicles of choice as the economies graduate from bank financing. That said, we next discuss convertible valuation.

BASIC CHARACTERISTICS OF CONVERTIBLE SECURITIES

The simplest convertible security, namely a traditional convertible bond, can be viewed from a fixed income investor's perspective as a combination of an otherwise identical nonconvertible bond plus a call option to exchange the bond for the underlying shares. From the equity oriented investor's viewpoint, it may be viewed as a combination of a long position in the underlying shares, a put option to exchange the underlying shares for an otherwise identical nonconvertible bond, and a swap to receive coupons of the convertible bond in exchange for dividends on the underlying shares. This is an immediate implication of the European version of the put-call parity theorem.[33] The introduction of redemption features and other embedded options in the more varied convertible structures discussed above may complicate, but does not invalidate, the basic equivalence concept.

Value Diagram and Descriptive Measures

Exhibit 42–2 value diagram shows the roles of debt and equity components in valuing a convertible security. The horizontal axis is the value of the underlying shares and equals the stock price times the conversion ratio. This value is called the convertible's *parity value,* or simply *parity*. The line ODQ also represents parity. ACDB is the value of the corresponding straight debt, and ACVS represents the value of the convertible bond. Because a convertible bond provides the investor with rights beyond those provided by an otherwise identical nonconvertible bond, in that it can be converted into the underlying shares, its value should equal or exceed the larger of the corresponding debt or parity. Accordingly, in the value diagram, ACVS is equal to or above the segment OD, where bond value exceeds parity, and is equal to or above DQ, where parity exceeds bond value.[34]

33. See John Cox and Mark Rubinstein, *Option Markets*. Englewood Cliffs, NJ: Prentice-Hall (1985) pp. 41–43.

34. The value of a convertible in a two-factor valuation model would be represented by a three-dimensional surface with the value of the convertible on the y-axis, stock price—the first factor—on the x-axis, and interest rates—the second factor—on the z-axis. The simpler two-dimensional representation above is, therefore, a section of the pricing surface parallel to the x, y plane, at a given level of interest rate plus credit-spread, and assumes a constant volatility level. On the other hand, the volatility surface of a convertible can be graphically represented if the interest rate plus credit-spread were to be held constant, while volatility, represented on the z-axis, is assumed to change with changing stock price levels.

EXHIBIT 42–2

Convertible Value Diagram

Three measures of premium are commonly used in convertible parlance. They are the conversion premium, the points premium, and the investment premium. The vertical distance between ACVS denoting the value of the convertible bond, and the bond floor (or investment value) line ACDB, represents the convertible bond value in excess of its investment value. This is expressed as the *investment premium,* defined as

$$\text{Investment Premium} = [(\text{Convertible Price} / \text{Investment Value}) - 1] \times 100 \quad (42.1)$$

The vertical distance between the convertible bond value ACVS and parity ODQ represents *premium over parity*. This may be stated in *points premium,* defined as the dollar value of the convertible bond minus the dollar value of parity, expressed as a percent of par. For example, if the bond price were $1047.50 and parity were $920, then points premium would be 12.75 points. Alternately, the premium may be stated as the *conversion premium,* defined as

$$\text{Conversion Premium} = [(\text{Convertible Price/Parity}) - 1] \times 100 \quad (42.2)$$

The conversion premium is 13.86% in the illustration above. Conversion premium, or simply, the *premium,* is an important and commonly used measure. Together with the investment premium and the notion of the *delta* of the convertible (defined below), the conversion premium helps characterize the change in the value of the convertible with a changing underlying share price.

The ratio of the change in the value of the convertible to the change in the value of the underlying shares, or parity, is called the convertible's *parity delta.* As does the equity call option delta, the parity delta ranges from zero to 1.0, and is the per share delta of the convertible. Therefore, it is also called the *delta,* or the *neutral hedge ratio;* the per share basis is the unstated assumption. At zero delta the convertible behaves like straight debt, and at 1.0 it behaves like common stock. Therefore, the delta of the convert may be viewed as the correlation of the change in the price of the convert to the price change in the underlying share. A 65% delta means that for small moves in the underlying share price of, say, \$0.10, the change in parity = the change in the price per share times the number of shares per convertible = \$0.10 × 6.621 = \$0.6621. The expected change in the value of the convertible bond then is = the change in parity times the hedge ratio = \$0.6621 × 0.65 = \$0.4304, or 0.0434 bond points. If an investor of the convert wanted to hedge the equity risk, she would in theory have to sell short.

Conversion ratio × delta = 6.621 × 0.65 = 4.3037 shares per bond
to establish a *delta neutral position.*

The neutral hedge ratio is the tangent to, and the slope of, the convertible bond valuation curve at a particular stock price. For infinitesimal moves up or down in the stock price from this initial level, a hedged portfolio consisting of long the convert and short the shares, as illustrated above, will result in neither a loss nor gain. For noninfinitesimal stock price change upwards, the gain arising from the long position in the convert will be lesser than the loss incurred due to the short position in the shares as the conversion premium declines.[35] In the event of a large move up, the ex-ante neutral hedged position turns out to be ex-post underhedged, and hence the loss. The reverse is true in a large down move in share price. In this case, decline in the convert price, all else being the same, will be lower than the gain on the short position in the shares as the conversion premium increases or "blows out". Viewed ex-post, the position was over-hedged. The main point to note is that a traditional convert is long an embedded equity call option and thus is a positive gamma security with respect to the underlying stock. On the other hand, like all callable fixed income instruments, it is also negatively convex with respect to interest rates.

35. Gamma is the second derivative of the convertible value with respect to parity, and is the rate of change of delta with respect to the share price is an important element in convertible trading. In times of high volatility such as what the markets have witnessed in recent years, gamma of each position, and its aggregation to the level of each trader's position and to the level of the firm, is an important risk measure of the entity's profit/loss potential. A positive gamma is always desirable and negative gamma "a Giffen good."

Stages of a Convertible Security

The price response of a convertible to a change in parity can be conceptually segmented into four stages or regions. These approximate regions are delineated in Exhibit 42–2. They are:

Balanced Converts

Several factors determine the conversion premium of a convert. Among the more important of these is the price response of a convert to changes in the underlying stock price and interest rates. Convertibles with conversion premium of 15% to 40%, and investment premium of 15% to 25%, respond materially to both. Their deltas range from roughly 55% to 75%.[36] Hence converts with these attributes, either upon issuance or subsequently as a result of stock price movements, are called *balanced convertibles*. Their upside/downside participation and risk/return tradeoff characteristics appeal to outright convertible funds and equity funds seeking a lower risk alternative or add-on position to common stock from an issuer with attractive equity fundamentals. All else being equal, lower the premium, more attractive the convertible from a buyer's perspective.

Equity Substitute Converts

The more the underlying stock price exceeds the fixed conversion price of a traditional convert, or, in the case of an accreting convert, the then effective conversion price, the deeper in-the-money is the convert. When such a convert's premium is about 15% or less, while its investment premium is higher than 40% it is referred to as being *equity like,* or as an *equity substitute*. It will respond sharply to changes in parity, and to a lesser extent to changes in the interest rates or interest spreads, and its delta is usually above 80% to 85%. Clearly, this movement is due to the investor put option to exchange the convert for its redemption price being now deep-out-of-the-money. While share price is the prime determinant of the value of a convert in this phase, it cannot be emphasized enough that other factors, such as remaining call protection and stock price volatility, also materially affect its value. The shorter (longer) the remaining call protection, the lower (higher) the conversion premium an investor would be willing to pay. Outright convert funds tend to sell the security at this stage in favor of other balanced converts while equity income funds tend to buy in this stage. Hedge funds' trading role increases along with stock price fluctuations, in what is known as *gamma trading*. With positive convexity feature of the convertible prominent at this stage, portfolio leverage and small net capital requirement due to the high delta, this stage of the convertible constitutes a potentially lucrative trading opportunity for hedge funds.

36. All else being the same, higher (lower) the credit-spread, lower (higher) the conversion premium. High bond floor makes the convert respond more to interest rates and less to equity.

Busted Converts

If the share price were to decline such that the conversion option were deep-out-of-the-money, and correspondingly, the put option deep-in-the-money, the conversion premium would increase while the investment premium would decline. The conversion premium in this stage is usually larger than 50% and may be as high as 200% or even higher, but investment premium is less than 15%. As the conversion option is worth very little, the convertible bond value approaches that of an otherwise equivalent nonconvertible bond. Its price falls to a level determined by the relevant yield measures. For traditional converts, those measures are the current yield and the yield to maturity. For the accreting converts they are the yield to put and/or yield to maturity. Outright convert funds exit their positions in these converts, to be replaced by fixed income funds seeking equity participation and hedge funds with credit analysis expertise. Credit risk may be offset by buying CDSs if they are available. In the absence of CDS on the particular issuer, proxy credit hedging methods include purchasing CDS of a similar credit in the same industry sector, shorting straight bonds of the issuer particularly if they are pari passu in seniority at a duration based hedge ratio, or buying equity puts or over-hedging by shorting more shares than suggested by the bond's equity delta. Some funds, though, may choose to retain exposure to the credit if their fundamental credit analysis or analytical models conclude that the risk/reward ratio is compelling, the yield give-up in exchange for the deep-out-of-the-money conversion option is relatively minor and, sometimes may even be negative, due to market inefficiencies in this region. However, fixed income funds that traditionally invest in senior or senior-subordinated bonds may not be reluctant to buy subordinated convertibles, nor do they generally buy busted convertible preferreds.

Distressed Converts

These converts may be considered a subset of the busted converts with the distinction that the stock price has fallen so far as to materially increase the probability of default. The ratings may be lowered either explicitly by the rating agencies or implicitly by the market as reflected in a substantial widening of its credit-spread or materially increased CDS premiums. Unlike the other stages in which the bond floor holds up reasonably well (see Exhibit 42–2) here the bond floor falls rapidly with the stock price. At this stage, the fixed income funds exit and *distress funds* or *vulture funds,* are the primary investors. These funds specialize in assessing the default probability and recovery rate estimation in the event of default. Both the conversion premium and the investment premium are very small to negligible in this stage. Interestingly, the gamma with respect to the stock price is extremely high as small changes in the low stock price may change the delta very significantly. Distressed funds may be long or short the convertibles based on the relative values of other senior or pari passu debt used as hedging instruments as well as depending on the availability and relative attractiveness of establishing deep-out-of-the-money protective put hedges.

Before leaving this section, some caveats are in order. First, the stages discussed do not have discrete boundaries. For instance, newly issued converts in Europe may have high conversion premiums but a low investment premium, and a delta in the region of 55% to 70%. This is due to the very high implied ratings of the investment grade converts resulting in a high bond floor. Second, convertible securities are not static, in that their price response changes and they may become more equity-like or debtlike with the attendant changes in the risk/return profile. Consequently, analytical tools for fundamental equity research as well as those for valuing fixed income securities and derivatives would be needed to select and manage a portfolio of convertible securities. Third, while the conversion premium is often used as a readily available measure to determine the current stage of the convertible, that is, whether it is a busted convert or in-the-money or something else, the more appropriate measure is the investment premium. For example, an in-the-money convert with extended period of remaining call protection, on a volatile, low dividend paying underlying stock can trade at substantial conversion premium. However, higher (lower) the investment premium, unambiguously more (less) in-the-money is the convert.

APPROACHES TO VALUATION OF CONVERTIBLES

In this segment, we discuss the traditional valuation method as well as the analytical—and more mathematically intensive modeling—approaches. The latter are increasingly more standard though it is not uncommon for investors to use both these approaches, to varying degrees to supplement each other.

Traditional Valuation Method

This approach is based on the premise that buying a convertible is the equivalent of buying common stock at a premium with the premium recouped over time from the difference between the higher income from the convertible coupon and the lower dividend on the underlying stock.[37] *Payback period* or break-even period is the principal metric employed in assessing the relative attractiveness of the convert versus the common stock. The shorter the payback period, the more attractive the convertible, especially if the payback period is shorter than the call protection period. As we shall see, the concept of payback period is flawed, yet this concept continues to be used by some equity-oriented investors as an adjunct to their fundamental analysis of the underlying stock. Unfortunately, this measure is not applicable to some of the newer structures, and may even prove misleading. Even within the traditional structures, most convertible new issues in the past decade would fail the payback period test. We will use the following example to explain the traditional valuation method.

37. Note the difference between this approach and the contingent claims approach, which views the convert as a combination of equity, a put option to exchange into straight debt, and the swap to receive coupons of the convertible for dividends on the underlying shares.

Consider a convertible bond issued at a par of $1,000 by PQR Corp. with 2.625% annual coupon and a five-year maturity that can be converted into 16.1421 shares of PQR common stock. Due to the appreciation of the stock price since its issue and the elapse of time—it now has about four years remaining to maturity—the bond currently trades at 121 (bond points, in percent of the par amount) and the common stock at $65.06. The common stock dividend has been, and is still, zero.

If an investor purchased one PQR convertible at 121 instead of buying the common shares equal to the conversion ratio of the note, she paid a premium of $159.75 (= $1,000 × 121 percent – $65.06 × 16.1421), or 15.975 bond points. However, this premium would be compensated for by the cash-flow differential between the convertible bond and the underlying shares:

$$\begin{aligned}&\text{Annual cash-flow differential}\\&= \text{Par amount} \times \text{coupon rate} - \text{Parity} \times \text{dividend yield}\\&= \$1{,}000 \times 2.625\% - \$1{,}050.25 \times 0\%\\&= \$26.25\end{aligned}$$

This implies that each year, the bond investor receives $26.25 more income than she would from dividends on the PQR common shares. Thus the payback period is:

$$\begin{aligned}&= \text{Premium paid/Annual cash-flow differential}\\&= \$159.75 / 26.25\\&= 6.09 \text{ years.}\end{aligned}$$

Simple derivation leads to the following formula for computing the cash-flow payback:[38]

$$\text{Cash-flow payback period} = [\text{Conversion Premium}/(1+ \text{Conversion Premium})]/ [\text{Current yield} - \{\text{Dividend yield}/(1+ \text{Conversion Premium})\}] \qquad (42.3)$$

where current yield refers to the current yield of the convertible. For the convertible the conversion premium was 15.211% and the current yield is 2.625% /121 = 2.169%, and the dividend yield on the common was zero. Using these inputs, Equation (42.3) results in the same payback period of 6.09 years. All inputs for the computation should be in decimals.

An alternate method of calculating payback period, though less defensible, is more commonly used. It is called the *dollar-for-dollar* payback. Under this method, the implicit question asked is, "If I were to invest the same dollar amount in buying the common shares as I would in buying the convertible, what would be the payback period of the premium?"

38. For convertibles with changing coupons or dividends, such as step-up convertibles, this formula does not apply. The payback period can be calculated by directly using the definition.

In the above example, if the same dollar amount were invested in PQR stock, one could buy $1,210/$65.06 = 18.5982 shares. The annual cash-flow differential would still be the same as before, as would the payback period under this method, on account of the fact that PQR pays no dividends. However, if the stock paid a significant dividend, the latter method would result in a longer payback period. The formula for this latter method can be derived as:

$$\text{Dollar-for-dollar payback} = [\text{Conversion Premium}/(1+\text{Conversion Premium})]/[\text{Current yield} - \text{Dividend yield}] \quad (42.4)$$

The denominator of Equation (42.4) is called the *yield advantage*. Note that the payback period of over six years is longer than the remaining maturity of the PQR convertible bond, which is about four years. Is this a valuation anomaly, or is the valuation approach lacking?

While the definitions of paybacks can be refined by using dividend growth rates and discounting the cash-flow streams, the basic flaw in the traditional valuation approach lies in its failure to consider the optionality embedded in the convert, i.e., in its assuming conversion into common stock with absolute certainty. In the case of the traditional convertible, bond investors have the right, but not the obligation, to convert should the stock price not exceed the conversion price, in which event they would receive par at maturity. And the meaning of payback period becomes even more problematic for accreting securities. For example, investors in zero-coupon convertible bonds do not receive current cash income. Thus, the convertible's income advantage would be zero or negative, and it's payback period could not be calculated. One may be tempted to substitute the yield to maturity or yield to the next put for the current yield. However, this again implicitly assumes a conversion probability of 100%, and excludes the possibility of default by the issuer.

Analytical Valuation Models

Virtually all valuation models for convertible securities currently in use by market professionals follow the economic framework of contingent claims analysis pioneered by Fischer Black, Myron Scholes, and Robert Merton.[39] The models differ from each other in the number of *stochastic variables* used in their construction.[40] The simpler one-factor model assumes that the stock price, or more correctly, the stock return, is the only underlying stochastic variable. All other items that impact on the value of a convertible are descriptors and variables.

39. See Fischer Black and Myron Scholes, "The Pricing of Options and Corporate Liabilities," *Journal of Political Economy*, May-June 1973, pp. 637–659; and Robert C. Merton, "Theory of Rational Option Pricing," *Bell Journal of Economics and Management Science*, Spring 1973, pp. 141–183.

40. A variable whose value changes over time in a nondeterministic or an uncertain way is said to follow a stochastic process.

The more complex two-factor models assume both stock returns and interest rates to be stochastic and are discussed below.

Descriptors and Variables That Affect Convertible Valuation

Descriptors are the attributes of a security that are known with certainty, such as its stated maturity, coupon, and call and put schedules. Variables are inputs that can be estimated, albeit with estimation error. Examples include future dividends and the costs involved in hedging the security. Descriptors that affect the value of a convertible security include:

- *Spot price of the underlying security:* The higher the stock price, the more the conversion option is likely to be in-the-money (or less out-of-the-money), and hence the higher the value of the convert.
- *The dividend yield of the underlying common stock:* The higher the dividend yield of the underlying stock, the lower the value of the convert as it results in a lesser yield advantage thereby reducing the attractiveness of the convert as an alternative to the common stock. Looked at another way, a higher dividend restrains the stock price appreciation and the convert's potential to go in-the-money. The same logic holds for the dividend growth rate. Most new issue converts have a dividend protection clause that compensates the investor in cash or decrease in the conversion price if the dividend payout on the common stock exceeds a prespecified level.
- *Coupon or preferred dividend:* The higher the distributions from the convert, the higher the yield advantage and hence the higher the value of the convert.
- *Issuer redemption:* A longer noncall period increases the value of the convert in two ways. First, the investor enjoys the yield advantage for a longer period. Second, absent a voluntary conversion by the investor, the minimum maturity of the conversion option equals the convert's first redemption date; hence the longer the conversion option, the higher the value of the convert. A hard noncall is worth more to the investor than a soft call of the same maturity.
- *Maturity:* Consider two converts identical in all respects except their maturity dates. The longer maturity convert will have the lower value. This may seem contradictory because we know that the longer the maturity of a call option, the higher will be its value. But while longer maturity does increase the value of the conversion option, it is swamped by the decrease in the value of the bond floor caused by discounting the cash-flow stream at a higher rate over a longer period. For deep-in-the-money converts, the direct impact of increasing rates is smaller because conversion value of the convert acts as the lower bound. However, if rate

increase impacts the stock price adversely, which is plausible, then the second order impact of rates on deep-in-the-money can also be negative.

- *Investor put:* Redemption at maturity is the equivalent of an investor put at maturity. A convert with a put prior to maturity will be worth more than one without. The earlier the put date, all else being equal, the higher the convert's value; also, the higher the put redemption level, also called the *put price,* the higher the convert's value.
- *Liquidity:* The more illiquid the convert, the lower the value of the convert as even moderate size trades are likely to materially change convert prices, causing sellers to realize less than they otherwise would and buyers to pay more. As seen during the 2007–2008 period, market illiquidity caused convert prices to fall quite dramatically as hedge funds needed to sell positions to meet client redemptions. Not surprisingly, the most liquid converts were the easiest to sell, although at discounted prices. Even though market volatility increased, the *implied volatility* of the convertible securities fell. In other words, the pricing curve of convertible in Exhibit 42–2 declined. Conversion premiums did "not open" or increase with declining stock prices—as would be expected under normal market conditions—during this period of illiquidity. Thus even positions held by better financially better situated funds and outright funds experienced mark-to-market looses. The notion of "illiquidity premium" became more relevant.
- *Borrow costs*: Increase in the cost to borrow stock effectively has the same impact as an increase in the dividend of the underlying stock. When the convert is illiquid and/or the stock borrow cost excessive, the convert may trade below parity, leading investors to voluntarily exercise their conversion option, which normally they would not. Outright investors are also affected as increased hedging costs to investment banks' trading desks are likely to result in wider bid/offers, smaller transaction sizes or accepting the outright investors' sell order on a "work the order," which entails the investor holding the position until another buyer is found and having to bear market exposure until the position is sold.
- *Country risk:* As with other non-domestic securities, country risk assessment needs to be balanced against economic growth potential in general, and that of the underlying stock in particular. Not surprisingly, therefore, there is generally less exposure to non-U.S. converts in most U.S.-based outright portfolios. International funds, specific regional funds, and hedge funds account for the bulk of the investment pool for non-U.S. converts as they they may have a wider array of securities to hedge currency risk as well as at least a part of the country risk. As a general rule, converts originating from countries with perceived higher country risk typically are issued at lower premiums, or equivalently, their equity volatility is not fully priced. On the other hand, converts from large

multinational firms, especially from the G-10 countries, are well received when the implied corporate credit rating is high and the country risk low.

Candidate stochastic variables used to model the value of a convert include:

- *Stock returns:* This is the most basic explanatory variable, and is part of all convertible valuation models. A single factor model assumes stock returns to be the sole stochastic variable and posits a behavior of stock returns and variance.[41] Not surprisingly, since volatility plays a crucial role in valuation of options, it does so too in the valuation of convertibles. Some models use a flat volatility as an input for all time and stock price levels, whereas the more sophisticated ones use a term structure of volatility, and yet others may also incorporate *option volatility skew* wherein the volatility estimate depends on the extent the option is away from the at-the-money strike at each stock price as the stock price evolves over time.
- *Interest rates:* Valuation models for bond options have interest rates as the main stochastic variable. Since the price dynamics of a convertible are also influenced to a considerable degree by the straight bond component and its convexities, it stands to reason that two-factor convertible models include interest rates as the second factor. Its volatility, called the *yield volatility,* is an estimated parameter, analogous to stock return volatility in the single factor model.

  As stated, higher interest rates reduce the value of the bond floor of a convert by discounting the convert's cash flows at the higher rate. The impact of interest rates on the embedded options is more complex. An increase (decrease) in the interest rate increases (decreases) the value of the conversion option, and the reverse for the option to put the convert, if there is an investor pre-maturity put feature. From the issuer's perspective, if the convert is out-of-the-money, higher (lower) interest rates will reduce (increase) the value of the issuer's call option, as it would entail financing the redemption value by new debt at a higher (lower) rate. In the case of in-the-money converts, which should in most cases be called as soon as possible, the issuer's incentive for a conversion-forcing call will increase with rising interest rates.
- *Credit-spread:* The lower the credit quality of the issuer, the higher the probability of default, and hence the higher the credit-spread. For example, a Baa3/BBB- rated issuer may have a credit-spread of 210 basis points for a five-year maturity subordinated debt. If the rating were a notch lower at Ba1/BB+, the spread could widen by a further

41. The common assumption is that the process governing stock price returns is a geometric Weiner process. Stock returns over time Δt are normally distributed with mean $\mu\Delta t$ and variance $\sigma^2\Delta t$, where μ and σ^2 are the instantaneous mean and variance of the stock price returns, respectively.

50 to 150 basis points or even wider.[42] Thus spreads impact on converts in the same direction as do interest rates. Credit-spread is increasingly viewed as a stochastic variable in its own right and its volatility is tracked very closely.[43] Development of liquid CDSs on individual corporate issues, standardization of swap languages, and liquidly traded index CDSs as well as asset swaps allow investors to hedge credit risk for a majority of investment grade issues and many non-investment grade issues. Credit-linked products are an exciting growth area for convertible investment and arbitrage trading as also in relative value capital structure and equity volatility trading.

- *Exchange rates:* Consider a US$ denominated bond—both par and coupon are US$ denominated—exchangeable into shares of a UK pound (GBP) denominated underlying stock. In addition to the equity risk associated with the investor's conversion option into the underlying ordinary shares, a U.S.-based investor is exposed to exchange rate risk because the shares are denominated in a different currency. With the number of shares per bond fixed, any increase in the value of the GBP against the US$ would benefit the investor, and any decline reduce the value of her position. Thus the investor thus has an embedded call on GBP, or equivalently, an embedded put on US$, in the convert.

Since exchange rates are stochastic, they could potentially be an additional factor in the valuation of a convert. Exchange rate volatility would have to be estimated.

Analytical Valuation Models and Factor Choices

Stand-alone analytical models to evaluate convertibles have developed far beyond the initial bond plus separable warrant approach and almost invariably draw on the contingent claims approach pioneered by Black, Scholes, and Merton. Early among them were those by Brennan and Schwartz[44] and Ingersoll.[45] The general approach is to develop a partial differential equation (pde) that applies to corporate securities and is based on the stochastic process or processes driving the return process for the underlying asset. Then boundary constraints relevant to the

42. The spreads could be even wider as the security, in this example, has crossed the threshold from being an investment-grade security to a non-investment-grade one.
43. The widening of credit-spreads globally, despite falling Treasury rates, during the Asian and Russian debt crises of the latter half of 1998 and the more recent global financial market illiquidity in 2007–2008 have further enhanced portfolio managers' sensitivity to credit-spreads.
44. Michael J. Brennan and Eduardo S. Schwartz, "Analyzing Convertible Bonds," *Journal of Financial and Quantitative Analysis* (1980) pp 907–929.
45. Jonathan E. Ingersoll, Jr., "A Contingent-Claims Valuation of Convertible Securities," *Journal of Financial Economics* (1977) pp. 289–322.

particular corporate security being valued, in this case the convertible, are applied to the pde. They include that the value of the convertible:

1. Be no less than its conversion value at any time except under the non-conversion period
2. Be the higher of par or the conversion value at maturity
3. Be no less than its "bond floor" or its recovery value upon default, whichever is lower
4. Be less than or equal to its redemption price during the redemption period for out-of-the-money convertibles
5. If putable, be higher than or equal to the put price discounted to the valuation date

Despite the appealing notion of viewing the convertible as a bond plus an added and separable option component—a view prescribed for accounting purposes by FASB—convertible bonds are more complicated as the options are often nonseparable except in the simple case of convertibles nonredeemable and nonconvertible until maturity, i.e., the issuer and investor options are all of the European type. Also distinguishing convertibles from a bond plus warrant is that an American-style conversion adds an interest rate option in favor of the convertible investor whereby the investor can turn in the convertible bond to satisfy the exercise price, even if the bond component is worth less than the exercise price, which usually equals the bond's par value. This *usable bond feature* of the convert is absent in a bond plus warrant. In the event of exercise prior to maturity, the warrant exercise price is payable in cash and equals the par value, never anything less.

Clearly, convertibles are complex securities. In the presence of the boundary constraints mentioned above, its pde does not lead to a closed form solution and instead requires computationally intensive numerical methods. Implicit finite-difference method and explicit finite-difference method are the commonly used finite difference approaches.[46] A special case of the explicit finite-difference method is the binomial method, by far the most widely used approach for derivative valuations. The computational load increases exponentially with each additional stochastic variable included in the valuation model. In the language of the binomial tree approach, the binomial tree becomes "very bushy" very quickly. Consequently, even in nonconvertible bond option modeling in which the interest rates for short maturity and long maturity are two eminently logical stochastic variables, most practitioners employ a single factor model for the short rate and assume the evolution of the long rate in relation to the short rate. The inclusion or exclusion of a stochastic variable, therefore, involves a tradeoff between theoretical elegance and/or incremental gain in accuracy on the one hand, and com-

46. There are Taylor series approximations for partial derivatives in partial differential equations. While the implicit finite-difference has better stability properties than does the explicit finite-difference approach, it is computationally more time consuming; explicit finite-difference method is more flexible and more easily understood.

putational costs and complexity on the other. Almost invariably, when input estimation errors are likely to swamp the computational precision achieved through the inclusion of an additional stochastic variable, investors spend more effort in improving the input estimates and opting for a simpler model.

Needless to say, the theoretical value of a security will be a function of the particular pde chosen, In the case of convertible valuation, a single factor model with the underlying stock return as the stochastic factor is most commonly used in practice due to the frequency and accurate recording of trading in common stock. In these cases, the interest rate and credit-spreads are assumed to be input parameters. Many models make adjustments—either heuristic or market-calibration based—to compensate for the attributes of stochastic interest rate lost in a single factor model. That said, two-factor models, with interest rates as the second factor, are gaining in popularity.

Virtually all models sacrifice the candidates for a third and/or fourth factor in favor of computational ease. For example, to avoid considering each of these as a separate stochastic variable, resulting in exponentially increasing computational expense and are excessively time-consuming (to the point of making them impractical), credit-spreads may be bundled together with interest rates, and the two together are assumed to follow a stochastic process. Analogously, the impact of exchange rates on a convertible with two currencies is similarly addressed by creating a synthetic price series comprising the underlying stock price, say denominated in GBP, multiplied by the exchange rate of dollars per GBP each day, and estimating the volatility of the price series thus generated in US$. As a proxy for the term structure of volatility of stock price returns, volatility is estimated by applying subjective corrections to historical and implied volatilities, and the estimate is assumed to be constant over the life of the security; in other words, a flat volatility is assumed. That said, use of volatility surfaces is not uncommon in assessing volatility arbitrage opportunities across related securities.

The theoretical elegance of a single valuation model that is based on the value of the firm as the underlying asset thereby resulting in a consistent paradigm to value all corporate securities—bonds, stocks, options and all other derivatives being special cases—is widely recognized. Despite that, separate and individual valuation models for each of the securities and assets of the capital structure continue to be the norm despite often inherent inconsistencies in their underlying assumptions. Chief among them is that the value of a firm is not a traded asset. Consequently, price observations are rarely, if ever, available, and their distributional properties cannot be empirically established. The complexities of the individual securities, and their correlations with each other, necessitate assumptions that are not always palatable. Nonetheless, progress has been made in modeling corporate securities as options on the value of the firm and some of these are available commercially.[47]

47. CreditGrades and Moody's KMV are two such models. One might arguably say that during the financial crisis of 2007–2008 these models did not fare well; the primary reason being that the estimates of future correlations based on historical estimates did not hold as realized correlations far exceeded estimated correlations.

Space considerations do not permit us to describe the details of the construction of the binomial tree and the backward induction.[48] Additionally, there are several "off-the-shelf" convertible valuation models available in the market. Not surprisingly, therefore, most trading desks subscribe to one or more of these models[49] and focus their attention on estimating the input parameters to these models. There is the unstated assumption that the technology of the model construction among the market competitors results in valuation outcomes within acceptable bounds of each other, given a common set of input parameter values.

Exhibit 42–3 displays the front page of one of such commercially available models, KYNEX convertible model.

EXHIBIT 42–3

A Convertible Analytics Model: Sample Page

48. Interested readers are referred to Kevin B. Connolly, *Pricing Convertible Bonds*. Hoboken, NJ: John Wiley & Sons (1998).

49. These models may also be available as part of a subscription service, such as Bloomberg, or available gratis from brokerage houses as client service provided with the expectation of trade execution through them.

Rates, Credit-Spreads, and Volatility Revisited

Since traders and portfolio managers are generally not the developers of the models, the nuances of the models need to be understood. This segment highlights issues, adaptations, and/or variations with respect to interest rates, credit-spreads, and volatility estimates deployed in the model development as they materially affect the value of the convert and the resulting trading/hedging recommendations.

Interest Rate

The interest rate input for each node of the binomial tree, used to solve the pde, is obtained from the derived zero coupon yield-curve from on-the-run Treasury securities or the LIBOR curve, with the latter being more frequently used as the benchmark rate. Some models may use a flat term structure. A flat credit-spread is also commonly used, though a term structure of credit-spreads based on CDS curves may be used to arrive at the credit-spreads, although there may not be as many data points to create the CDS curve.

Several models use a single interest rate adding together the (LIBOR) benchmark rate as well as the spread. This makes the resulting models more analytically tractable and the results conform to the put-call parity theorem. However, there is a problem. Consider a convertible that is separable into a bond and a warrant. Using a single interest rate, equal to the Treasury plus the applicable spread in valuing this convertible implies that both the bond component and the warrant component are discounted at the same rate. Warrants and options, however, when traded separately, do not use the credit-spread in their valuations because the risk neutral valuation approach of derivatives is independent of the default risk of the underlying stock. When the single rate is used, it tends to overvalue the embedded net conversion option. To achieve consistency with the option markets, the benchmark rate alone is used for the optionality and the benchmark rate plus the spread for the coupons and par. In practice, the short equity position in a hedged portfolio earns the short term riskless rate and not the benchmark rate plus the spread rate used to discount the cash flows of the convertible. Note that the put-call parity attribute is then lost.

A further modification of the two interest rates is to use a hedge ratio weighted mix of the benchmark rate and the benchmark rate plus the credit-spread. If the convert is deep-out-of-the-money, the probability of conversion is very low and the convert behaves like straight debt; its delta equals zero. Hence all cash flows associated with the convert are discounted at the benchmark rate plus the credit-spread. At the other extreme, when the convert is deep-in-the-money, the probability of conversion is very high and the convert behaves like a common stock; its delta equals 1. With a 100% hedge, the probability of loss vanishes and the portfolio should earn the benchmark rate. At intermediate points, the weighted average rate, weighted by the delta at the node, is employed.

Credit-Spread

The ideal input to the model is an *option-adjusted spread* applicable to the security. However, this information is seldom available. Due to the rapid and still growing importance and liquidity of CDSs, they have become the prime

input proxy source for credit-spread estimation. In addition to variations mentioned above, some models allow users to parameterize the credit-spread as a function of the stock price level. The logic is that as stock price rises (falls), its debt to equity ratio falls (rises), and hence the credit-spread should decline (increase) correspondingly. However, the speed and process of the corporate credit-spread adjustment to the stock price change is yet unknown and may evolve at different paces for different securities and times. Hence this adaptation, although elegant, is to be used with caution and largely for risk scenario assessments.

Stock Volatility

In any contingent claim model, an estimate of the future volatility likely to occur during the life of the contingent claim security is the required input. Volatility estimation is even more critical for the very long dated options embedded in converts. Among the sources to estimate this parameter are:

1. Historical volatility for periods ranging from 1 month to 12 months, and their trend.
2. The implied volatility trends for listed options and *LEAP*s and index options with maturities longer than 9 months. Particular attention is paid to the *implied volatility skew*.
3. The implied volatility of existing converts from the same issuer.
4. The implied volatility of converts in the sector.
5. Volatility implied in the pricing of CDS of the issuer (or close proxies) matching the first put date or maturity of the convertible.

A downward adjustment is warranted to the resulting estimate if the common stock and/or convert are not likely to be liquid; very high volatility estimates, above 40%, are usually capped in anticipation of volatility mean reversion.[50]

Applying the Valuation Model

The most common application of the valuation models, not surprisingly, is to estimate the theoretical worth of a security at any point in time. If the theoretical value is, say, 104.5, and the security is trading at par, it is said to be 4.5% cheap. Other equivalent ways to view this cheapness or richness is through the implied

50. A more elaborate method for estimating volatility is the generalized autoregressive conditional heteroskedasticity (GARCH) approach, which gives progressively increasing weight to more recent observations of volatility. The weighting scheme is defined by an estimated decay parameter, analogous to the mean reversion parameter in interest rate models. See Tim Bollerslev, "Generalized Autoregressive Conditional Heteroskedasticity," *Journal of Econometrics,* 1986, pp. 307–327.

volatility or the implied credit-spread or the implied option adjusted spread. This cheapness/richness estimate depends, of course, on the inputs and the particular valuation model employed. A valuation model will need to be calibrated periodically against market prices of liquid converts to catalog its biases. After this initial calibration, most practitioners are more concerned with the consistency of the model than with its absolute accuracy. The trading task is made easier when the model also provides scenario analyses—for varying input parameters of holding period horizon, rates, spread, volatility, changing richness/cheapness from current situations—and also built in portfolio management, risk analytics, and trade execution systems. Most analytical trading models provide for these features, including the one cited above.

Theoretical rich/cheap analysis is but one of the inputs to determine whether a convertible is a buy or a sell candidate. Additionally, its relative attractiveness compared with other available opportunities, its risk/expected return profile and its contribution to the portfolio as a whole also need to be considered. We discuss some of analytical items among these next.

Partial Derivatives

The partial derivatives commonly used in monitoring equity and bond derivative risk/reward profiles are also applicable here. Briefly, in addition to the hedge ratio or delta, the other partial derivatives, collectively called the *greeks,* one needs to pay attention to are:

- *Theta:* The time decay of the value of the options embedded in the convertible, especially for its short maturity options, such as during the *redemption notice period*[51] or close to the mandatory conversion date or maturity.
- *Vega:* High volatility underlying shares, such as those in the Internet, technology, and telecommunication sectors carry the risk of volatility collapse, more specifically, collapse of implied volatility. Illiquidity driven implied volatility collapse devastates the premium and the value of convertibles. This has occurred episodically such as during 1994, the Asian, Russian, and emerging market crises of 1998, in 2005 in the U.S. and, most painfully globally, in 2007–2008. Vega estimates for a position or portfolio's potential profit/loss exposure to sudden large moves are common in risk reports. Most non-directional hedge funds hedge their Vega exposure.
- *Gamma:* This measure of convexity or rate of change of delta is a very closely watched second derivative and deserves elaboration. A negative

51. The redemption notice period is the prespecified number of days, usually, 15 to 30 days, following the redemption notice by the issuer, during which period the holder needs to exercise the conversion option, failing which the holder is deemed to have opted for the redemption amount.

gamma position resulting from short option positions such as writing a put or writing a call, or shorting a convertible, can quickly cause significant losses in the event of large up moves in the underlying. A long position in a deep-in-the-money convertible that is delta hedged by a short stock position, on the other hand, is a positive convexity position due to its equivalence to a long put position. However, a long convertible bond, unless credit hedged by long CDS position, is equivalent to a short credit convexity or credit gamma as the investor is exposed to the credit risk of the bond. The concepts of credit duration or credit delta, credit gamma, and credit volatility are now integral parts of the risk metrics that guide convertible trading and capital structure arbitrage.

- *Rho:* This measures the change in the value of the convert due to a small change in the interest rate and credit-spread. As the volatility of interest rates or *yield volatility* has increased, traders and investors need to be aware of the interest rate duration and negative convexity embedded in the convertible and deliberate decisions need to be made about retaining or hedging away these risks via interest rate futures or options. *Credit-spread delta,* or simply, *credit delta* is an important trading and risk metric to monitor and separate interest rate risk from the credit risk of the position.
- *Cross partials:* These are second order, although important, risk elements. We discussed the impact of a change in stock price on the credit-spread of the bond; the other is on equity volatility skew. Estimating these is still an art with no easy solutions.

Implied Default Probability and Implied Recovery Rates

An investor can hedge the credit risk of a convertible (or straight bond) via an appropriate long CDSs position with the bond as the reference security. Asset swaps, on the other hand, are used to hedge both the rate risk of the coupon payments as well as the credit risk of the bond. Implied in the pricing of the CDSs and asset swaps are estimates of default probability and asset recovery rates in the event of default.

Implied Volatility and Implied Credit-Spread

From the investor's relative value analysis perspective, higher (lower) the implied volatility of the convert compared to the historical volatility of the underlying stock, richer (cheaper) is the security. Similarly for credit-spread implied by convertibles are compared with those of comparable converts and straight bonds.

While metrics regarding implied volatility, credit-spread, default probability and recovery rates are useful, some caution is in order regarding their interpretations. First, estimates of "the implieds" are conditioned on the validity of all

inputs into the model and the valuation model itself and are not to be thought of as "absolute estimates." Furthermore, there is an element of circularity in sequentially estimating them using the same set of inputs. Second, it is well known that the value of a convertible is most sensitive to volatility when the convert is near the money, and to credit-spread when deep-out-of-the-money; it is less sensitive to either when deep-in-the-money. Misleading implied volatility estimates/conclusions may result if one is not mindful of, or control for, the skews or maturities of the embedded options.

EXERCISING THE EMBEDDED OPTIONS

In this section, we discuss the decisions facing investors and issuers with respect to the options embedded in the convert. Clearly, there are some game-theoretic aspects to the anticipatory or responsive actions taken by the two parties.

Investors' Options

Conversion Option

With the conversion privilege terminating at the expiration of the redemption notice period, the question is when during this period should the investor tender the bond for conversion, assuming that it is in-the-money. Following the redemption notice, if the stock price falls below the effective per share redemption price,[52] the investor can choose to receive the redemption price. Thus, the redemption notice triggers a knock-in put, with maturity equal to the number of days in the redemption notice period. Due to the embedded long American conversion call option, under normal circumstances premature exercise is suboptimal when the underlying stock does not pay any common dividend. For dividend paying underlying stock, premature exercise of an American call is warranted when the present value of the dividend stream during the life of the call exceeds the present value of interest likely to be earned on the exercise price. This roughly implies that voluntary conversion of a convertible is rational when the dividend yield on the common exceeds the current yield on the convert, and the yield advantage becomes negative.[53] These situations seldom arise.

Therefore, by deferring the decision to exercise either option until the moment before the expiration of the redemption period it will be evident whether

52. Effective conversion price is defined as the redemption price divided by the conversion ratio. For example, if the bond is redeemable at 103.5 and the conversion ratio is 14.865 shares, the effective conversion price is \$1035/14.865 shares = \$69.627 per share, although the conversion price is \$1000/14.865 shares = 67.272 per share. In the case of accreting securities, it is the accreted price divided by the conversion ratio.

53. We say "roughly" because some converts on high dividend yielding stocks have been issued with negative yield advantage. Investors correctly view them as equity with very valuable puts, and hence, as very defensive securities.

the conversion option is worth more or the redemption option and choose accordingly. Investors who elect to sell their convert during the redemption notice period can find ready buyers among convertible arbitrage funds who will usually pay some value for the remaining optionality, less their transaction cost. Occasionally, voluntary conversion may occur when the stock borrow cost is very large, and thus has the same effect as a negative yield advantage. The voting right of a common share will rarely be the reason to voluntarily terminate the life of the convert and receive the shares.

Finally, absent a redemption notice, premature conversion may be rational if the underlying price exceeds the *critical stock price*. That price level of a dividend-paying stock at which the yield advantage for the convert is negative, and the value of the put option exactly equals the absolute value (of the now negative value) of the swap to receive the coupon in place of dividends, is called the critical stock price. At this point, conversion premium is zero, making the investor indifferent between holding the convert or receiving common stock upon conversion. Higher the dividend yield, lower the critical stock price. For most stocks, this point is approximately at 175% of the conversion price.[54]

Put Option

Exercise of a putable convert is rational if the estimated value of the convert immediately following the next put date is lower than the put price. Some issuers want to know the scenarios under which the convert will be put to them, and this can be an important consideration in their choice of financing instrument. With a view to defer put exercise, an issuer may, voluntarily and unilaterally, insert an additional put, at an appropriate price, immediately following the next put in the existing put schedule of the convert. This is called a *put extension sweetener*.

Change of Control Put Option

Most converts include an investor put at par, or slightly above par, in the event that a specified percent, usually 51%, of the shares of the underlying stock is acquired by another entity. The put price is payable in cash and has the deterrent effect of a poison pill, particularly if the convert is out-of-the-money. For those trading above the put price, the put exercise results in the loss of the conversion premium in excess of the put price, and the convert is terminated. Quite often, the acquirer's common stock will replace the target firm's common shares according to a specified exchange ratio. This will preserve the conversion option and some, or all, of the conversion premium. The decision rule for investors, as always, is to choose the value-maximizing alternative. Depending on the circumstances, value maximization may or may not entail exercising the change of control put and especially so if the convertible structure includes a *takeover protection clause* that makes the investor whole in the event of a change of control event.

54. This may explain why following a hard noncall period, a year of provisional call protection at 175% or higher is roughly worth equal to another year of hard call protection.

Issuer's Options

The optimal issuer action is to minimize the gain of the convert investor and maximize the benefit to the shareholder. Conceptually, in the absence of the redemption notice period, the optimal redemption moment is exactly when parity equals the redemption price. Since the redemption notice period does exist, the optimal decision, and its timing, becomes a function of the issuer's intent and of whether the convert is in-the-money and by how much. If the issuer is indifferent to whether the issue converts or is redeemed for cash, then the issuer's optimal decision will be to redeem at the earliest opportunity. This situation occurs when the convert constitutes an insignificant component of a large firm's balance sheet and/or refinancing is readily available at lower net costs. The most common issuer options are:

- *Conversion forcing redemption:* The benefits to the shareholder of forcing conversion include saving the interest expense, lower leverage, and an increase in debt capacity due to the additional equity in the balance sheet resulting from the conversion. If the after tax cost of the coupon on the convertible is lower than the dividend yield, or in the case of accreting converts, if the after tax cash flow is positive to the issuer, the issuer may choose to defer redemption. Given the redemption notice period, the issuer needs to allow for a margin of safety such that the probability of the stock's falling below the effective conversion price is at an acceptable level. The greater the risk aversion of the issuer to the adverse effects of nonconversion, the higher will be the cushion, and results in what is known as the *call delay*. The negative impact of a failed attempt at forcing conversion may be severe; and in smaller firms it may lead to financial distress. At the very least, the issuer will have to refinance the redemption value with cash or debt and thereby cause the capital structure to be different than intended. Alternately, the issuer may have to pay—a usually unwilling—investment bank to write a put guaranteeing conversion. Such puts are difficult to hedge and banks are therefore reluctant to sell them. Even if they do so as a favor to the client, these puts are expensive due to the large gamma and event risk. Greater the call delay, higher the value of the convert. Call delays have declined over time and are currently in the 15% to 30% region today, and are a function of the volatility of the underlying stock, the length of the redemption notice period, and the issuer's risk aversion.[55]

55. Specifically, it is equal to $\sigma\sqrt{t}$, where σ is the stock's volatility estimate for the period, and t is the length in years of the redemption notice period. As a numerical illustration, if t is one month, the short term volatility estimate is 0.30 per annum, and absent any jumps, the stock is expected to move $0.30 \times \sqrt{(1/12)} = 0.866$, that is, ±8.66% in one month with a probability of 68%. The two standard deviation, or equivalently, a 95% confidence interval implies a call delay of $2 \times 8.66 = 17.32\%$ above the effective conversion price, assuming a log-normal return distribution for the stock price.

- *Debt refinancing redemption:* If the issuer does not want conversion to occur, the logic of the call delay also applies here, except that now the stock price has to be below the effective redemption price so as to provide the desired cushion. The issuer's reasons for redeeming the convert for debt may include reduction in equity dilution, refinancing at a lower rate and/or extending maturity. The cost of debt of matching seniority and maturity is the appropriate benchmark from a cost of capital perspective.
- *Put extension sweetener and co-pays:* As discussed, in situations in which it is economically optimal for investors to exercise a put option but the issuer does not want the put exercised, put extension sweeteners are used. In addition knock-in payments may also be used.
- *Issuer buybacks:* Often illiquid or deep-out-of-the-money convertibles or convertibles with heavy carry costs (dividends and cost of stock borrow) are presented to the issuer by hedge funds interested in selling the bonds back to the issuer in exchange for a sweetener to where the bonds may be trading or are marked. By buying these bonds back in one-off transactions and mindful not to trigger a "creeping tender" violation of SEC regulations, the issuer can lower his debt/equity ratio as well as recognize a gain for buying the bond back under par. Typically, the sweetener can range from half a bond point to three bond points above the estimated value or mark of the convertible and is paid in either cash or equivalent increased number of shares as agreed upon by the two parties.

LOOKING FORWARD

Despite the growth trajectory of the convertible asset class there have been hiccups along the way making many investors uncomfortable with its complexity and periods of illiquidity. Analytical and structural diversity as well as its market efficiency have been aided by a leading, if not a dominant role from time to time, by hedge funds and institutional investors. With hedge funds being the most active traders in convertible secondary markets, it is easy to view them as the marginal trader that drives pricing. What then are the risk/return and funds flow implications on the convertible asset class of hedge funds and of the development of risk mitigating products such as asset swaps and credit default swaps?

Hedge Funds

Issuers generally dislike, but are gradually getting used to, this class of investors as they are seen to exert downward pressure on the stock when they buy the convert and short the stock. And the number of shares shorted increase as the stock price increases. However, the point often overlooked is that hedge funds also support the stock were it to decline. In this event, they would buy back the stock to

reduce their hedge ratio and arrive at a lower neutral hedge position. The structured convertible, described above, is a strong case in point. Thus hedge funds contribute to volatility stabilization of the underlying share. Imagine a situation in which shorting the stock were not permitted, as was periodically enacted in different countries during the 2007–2008 crisis period. With these sudden proscriptions of short-sales, there was an immediate drop and severe disruption in the markets, broadly and even deeper for convert products. The liquidity providing role of hedge funds was immediately reversed and they became liquidity seekers who needed to raise cash in light of fund redemptions by their own fund investors. Only when the short-sale restrictions were removed and liquidity returned to the market did convertibles rebound in 2009 and new issuance began to take off as issues again accessed this asset class.

Empirical research documents a 2% to 3% decline in the underlying shares upon conversion of a convertible security, and this decline typically reverses itself in the following two to four weeks. This may largely be due to the short positions in the underlying by hedge funds against their positions in deep-in-the-money converts. In effect, the associated hedging is equivalent to preconverting over time so that the single day rush to the exits that would have otherwise occurred does not occur. Furthermore, over the recent years, the fund flows into hedge funds have helped issuers sell new issues via overnight transactions, thereby eliminating the market exposure that otherwise would have to be borne by the issuer due to the time-consuming customary road shows for a new issue transaction.

Asset Swaps

In a convertible security asset swap transaction a fixed income fund or a financial institution takes on the interest rate and credit risks embedded in the convert while the convertible holder, typically a bank trading desk or hedge fund, retains the equity optionality. Most common are the callable asset swaps on the underlying convert with a back-to-back redemption wherein if the issuer redeems the convert the trading desk may redeem the convert from the asset swap buyer. Until then the cash flows of the convert are passed through to the asset swap counterparty while the convert holder retains the equity optionality. This separation of the fixed income risk from the equity optionality of the convert makes the market more efficient by segmenting the elements of risk and trading in them by participants specializing in assuming and valuing these risks. It also helps provide liquidity to the busted converts, subject to credit quality constraints, and to new issue investment grade converts, which may be larger as a result. As the growth of the CDS product continues, however, asset swaps as applied to convertibles is expected to continue to decline.

Credit Default Swaps

The development of CDSs has helped bring ever closer corporate debt and equity liabilities trading via the "bridge products" such as convertibles. Capital structure

arbitrage is one such outcome. Already, in several leading investment banks, credit derivative desks are either integrated with, or are physically located in proximity of, convertible trading desks. Equity derivative desks are also similarly situated. Integrated approaches to valuing corporate liabilities is an exciting development phase and should result in creation of newer derivative products with the aim of isolating in even finer granularity the embedded risks in the securities and allowing a portfolio manager to make deliberate choices of retaining or hedging away some of these risks thereby resulting in more efficient and liquid markets.

Growth Markets and Distressed Markets

As discussed earlier, convertible issuance and asset class growth is most conducive when accompanied by growing economies and sectors. It is not surprising, therefore, to evidence more convertible issuance, albeit from a small base, from the more rapidly growing global economies of Asia and elsewhere while the U.S., the developed Western-European economies, and Japan remain the mainstays—despite their slower economic growth—due to their developed financial markets. But, in time, this balance too is expected to change. The versatility, range and usefulness of the convertible product was demonstrated that on the one hand when it was used to stabilize the balance sheet of distressed companies, as in the case of Citicorp mandatory at the depth of its crisis period, and on the other as growth stage financing for SanDisk in 2010. This flexibility too is expected to continue and develop further.

KEY POINTS

- Convertibles are fairly complex securities with several interwoven embedded options.
- They span the space between equity and debt securities. As a result, innovative flexible structures have evolved to address issuer and investor needs and also to address regulatory, accounting, and tax considerations. This flexibility will continue to ensure its presence as an important security in the corporate capital structure.
- To understand their nuances, tradeoffs and values, traditional methods of evaluation, in conjunction with the contingent claim valuation approach, need to be employed.
- In practice, both approaches are employed together with the fundamental equity and credit analysis of the underlying equity and debt for trading, hedging, portfolio and risk management of these equity-linked securities.
- Convertibles issuance is more attractive in high interest rate environments or when other modes of financing, such as bank financing, debt, or equity are either difficult or undesirable.

- While a majority of the convertible issues are noninvestment grade or unrated, they still constitute a meaningful avenue for capital raising by investment grade issuers and are capable of financing multibillion-dollar issues without extra effort.
- Convertibles are a much smaller asset class than equities and debt and their issuance volumes and trading are quite sensitive to market liquidity. And yet, when severe balance sheet repair is needed, the convertible market remains an attractive avenue to explore.

CHAPTER
FORTY-THREE

CREDIT ANALYSIS FOR CORPORATE BONDS

MARTIN FRIDSON, CFA
Global Credit Strategist
BNP Paribas Asset Management

FRANK J. FABOZZI, PH.D., CFA, CPA
Professor of Finance
EDHEC Business School

ADAM B. COHEN, J.D.
Founder
Covenant Review

The purpose of this chapter is to provide a framework for the credit analysis of corporate bonds. Although there are numerous types of corporate bonds outstanding, three major issuing segments can be differentiated: industrials, utilities, and finance companies. This chapter will deal primarily with industrials in its general description of bond analysis and then discuss utility and finance issues. Special factors that must be considered in the credit analysis of high-yield corporate issues are addressed. At the end of this chapter, credit scoring models for identifying potential issuers that may default are described.

APPROACHES TO CREDIT ANALYSIS

Traditionally, credit analysis for corporate bonds has focused almost exclusively on the default risk of the bond—the chance that the bondholder will not receive the scheduled interest payments or principal at maturity. This one-dimensional analysis concerned itself primarily with the calculation of a series of ratios historically associated with fixed income investment. These ratios typically would include fixed charge coverage, leverage, and funds flow/total debt. Such an approach was deemed appropriate when interest rates were stable and investors purchased bonds with the purpose of holding them to maturity. Under those conditions, fluctuations in the market value of the bonds owing to interest-rate changes were minimal, and fluctuations owing to credit changes of the bond

Parts of this chapter are based on the chapter by Jane Tripp Howe that appeared in previous editions of this handbook.

issuer were mitigated by the fact that the investor had no intention of selling the bond before maturity. During the past four decades, however, the purpose of buying bonds has changed dramatically. Investors still purchase bonds for security and thereby forgo the higher expected return of other assets such as common stock. Increasingly, however, investors buy bonds to trade them actively with the purpose of making a profit on changes in interest rates or in absolute or relative credit quality. The second dimension of corporate bond credit analysis addresses the latter purpose of buying a bond. What is the likelihood of a change in credit quality that will affect the price of the bond? This second dimension deals primarily with ratios and profitability trends, such as return on equity, operating margins, and asset turnover, generally associated with common stock analysis. Both dimensions should be applied in corporate bond analysis because they address the same issue—default or credit risk–from complementary perspectives. Only by using both dimensions of credit analysis will the analyst address the dual purpose of bondholding: security of interest and principal payments and stability or reduction in credit risk during the life of the bond.

Another outgrowth of the shift from buy-and-hold strategies to active bond management is a premium on prompt responses to news that affects a company's ability to generate cash flow to cover its interest charges. A sudden leap or plunge in stock price may reflect significant new information about a company's future profitability that the bond market does not yet reflect. By taking a clue from the equity market, an astute investor may get a jump on competitors in catching an upswing or avoiding a downswing in the issuer's bonds.

Beyond this sort of reactive approach, bond investors can use equity-based information to conduct systematic and potentially profitable analysis. The idea that stock analysis and bond analysis are intertwined has been advanced by the development of options analysis.[1] Underlying this line of reasoning is the basic insight that all of a company's liabilities derive their value from the same set of cash flows. This suggests that the intrinsic value of the equity must be consistent with the intrinsic value of the debt. (Note that the equity value referred to here is economic value, rather than the accounting value represented on the balance sheet by shareholders' equity.)

The ability to derive analytical benefits from these insights springs from the expectation that the company's owners will cease paying interest, that is, default on their debt, if the value of their equity drops to zero. This rational response is analogous to homeowners whose mortgages exceed the value of their houses "mailing the keys to the bank" instead of continuing to make interest payments. It follows that the bigger the equity cushion beneath bondholders, the more remote is the probability of default.

Exhibit 43–1 supports the argument that a large equity cushion, as measured by the company's valuation in the stock market, implies a small likelihood of default. The table ranks 22 U.S. investment-grade chemical companies by the ratio of market value of equity to total liabilities (MV/TL). A relationship between

1. Credit risk models, discussed in Chapter 45, are referred to as "structural models," "asset-value models," and "firm-value models."

EXHIBIT 43–1

Stock-Based Credit Comparison of Investment-Grade Chemical Companies

Name	Mkt Val/TL	Rating
Mosaic Co.	8.54	BBB-
Sigma-Aldrich Corporation	7.86	A
Monsanto Co.	4.81	A+
Ecolab Inc.	3.88	A
Albemarle Corp.	3.26	BBB
Praxair Inc.	3.25	A
The Sherwin-Williams Company	3.19	A
FMC Corp.	2.81	BBB+
Lubrizol Corporation	2.59	BBB+
Westlake Chemical Corp.	2.48	BBB–
Air Products & Chemicals Inc.	2.45	A
International Flavors & Fragrances Inc.	2.37	BBB
HB Fuller Co.	1.97	BBB
Airgas Inc.	1.94	BBB
Cabot Corp.	1.55	BBB+
Eastman Chemical Co.	1.52	BBB
The Valspar Corporation	1.50	BBB
RPM International Inc.	1.48	BBB–
EI DuPont de Nemours & Co.	1.47	A
Cytec Industries Inc.	1.31	BBB
PPG Industries Inc.	1.31	BBB+
The Dow Chemical Company	0.87	BBB–

Constructed from data obtained from Capital IQ.

the equity valuations and the corresponding bond ratings is apparent. The top half of the rankings includes six of the seven companies (86%) rated within the single-A category. The bottom half includes 10 of the 14 companies (71%) that are rated within the triple-B category.

The alignment is by no means perfect, however. Most strikingly, Mosaic has the highest MV/TL ratio in the group (8.54×) and the lowest rating (BBB–), whereas DuPont ranks 19th in MV/TL, yet has the second highest rating (A). Anomalies of this sort may help to identify a bond that is misrated, perhaps because the rating agencies have not yet fully responded to changes that the equity market has incorporated into the company's share price. Indeed, Mosaic rose from BB to BBB–at Standard & Poor's between October 2004 and

June 2008. That left the rating one step lower than Moody's equivalent Baa2, which Mosaic reached in August 2009 following a long climb from B1 in November 2006. Perhaps the rating agencies were being more deliberate than the equity market in recognizing a genuine reduction in default risk at the company.

Drawing a definitive conclusion, however, requires more than a simple comparison of a company's credit rating and stock valuation. Other factors could explain the ratings disparity between Mosaic and DuPont. For one thing, potash and phosphate producer Mosaic has a much less diversified product line than DuPont, and its earnings are highly sensitive to volatile commodity prices. In addition, Mosaic's stock price shot up dramatically in 2010 after an attempted takeover of Potash Corp. by BHP Billiton focused investors' attention on the value of potash reserves. This effect could have proved temporary. A long-run view of default risk might favor DuPont, despite the near-term restraint on its earnings imposed by a slow economic recovery in 2010.

More generally, the probability of default is a function not only of the equity cushion's size, but also its volatility. A company with a comparatively small equity cushion may receive a fairly high rating if its stock price is exceptionally stable. An extremely steady share price makes the company's equity value very unlikely to fall to zero and trigger a default.

A final caveat on the interpretation of equity valuations in the context of credit analysis is that under certain circumstances an increase in the equity cushion can indicate *increased* risk of default. The ultimate effect of a leveraged buyout (LBO) is that a substantial portion of the equity in the company's capital structure is replaced by debt, resulting in substantially heightened credit risk. For example, SunGard Data Systems fell from BBB+ to B+ at Standard & Poor's in connection with its 2005 LBO. To effect the transaction, however, the LBO sponsor must pay a premium to prevailing market value to acquire the stock from the existing shareholders. Sometimes, word of the pending LBO leaks into the market before the deal is announced, pushing the share price higher. That results in a short-run increase in the equity cushion, but analysts who leap to the conclusion that credit risk is declining will receive a rude surprise when the true cause of the price appreciation comes to light.

INDUSTRY CONSIDERATIONS

The first step in analyzing a bond is to gain some familiarity with the industry. Only within the context of an industry is a company analysis valid. For example, a company growing at 15% annually may appear attractive. However, if the industry is growing at 50% annually, the company is competitively weak. Industry considerations can be numerous. An understanding of the nine variables discussed in this section, however, should give the general fixed income analyst a sufficient framework for properly interpreting a company's prospects:

- Economic cyclicality
- Growth prospects

- Research and development expenses
- Competition
- Sources of supply
- Degree of regulation
- Labor
- Accounting
- Event risk

In some industries, for instance, an analysis of labor costs must consider technological advances that have made it feasible to outsource certain functions to lower-wage countries. Examples include handling of customer inquiries, analysis of diagnostic results, and financial statement analysis. Also, cross-border differences in accounting standards complicate credit quality comparisons of industry peers domiciled in different countries.

Economic Cyclicality

The economic cyclicality of an industry is the first variable an analyst should consider in reviewing an industry. Does the industry closely follow gross domestic product (GDP) growth, as does the retailing industry, or is it recession-resistant but slow-growing, like the regulated electric utility industry? The growth in earnings per share (EPS) of a company should be measured against the growth trend of its industry. Major deviations from the industry trend should be the focus of further analysis. Some industries may be somewhat dependent on general economic growth but be more sensitive to demographic changes. For example, the aging of the U.S. population should cause demand for health care to grow faster than the economy as a whole. Analysts must bear in mind, however, that efforts by government and employers to control health care costs may limit revenue growth. Other industries, such as banking, are sensitive to interest rates. When interest rates are rising, the earnings of banks with a high federal funds exposure underperform the market because their loan rates lag behind increases in the cost of money. Conversely, as interest rates fall, banking earnings outperform the market because the lag in interest change works in the banks' favor.

In general, however, the earnings of few industries correlate perfectly with one economic statistic. Not only are industries sensitive to many economic variables, but often various segments within a company or an industry move countercyclically or at least with different lags in relation to the general economy. For example, the housing industry can be divided between new construction and remodeling and repair. New construction historically has led GDP growth, but repair and remodeling have exhibited less sensitivity to general trends. Therefore, in analyzing a company in the construction industry, the performance of each of its segments must be compared with the performance of the subindustry.

Growth Prospects

A second industry variable related to economic cyclicality is the growth prospects for an industry. Is the growth of the industry projected to increase and be maintained at a high level, such as in the nursing home industry, or is growth expected to decline, as in the defense industry? Each growth scenario has implications for a company. In the case of a fast-growth industry, how much capacity is needed to meet demand, and how will this capacity be financed? In the case of slow-growth industries, is there a movement toward diversification or a consolidation within the industry, such as in the railroad industry? A company operating within a fast-growing industry often has a better potential for credit improvement than does a company whose industry's growth prospects are below average. However, barriers to entry and the sustainability of growth must be considered along with growth prospects for an industry. If an industry is growing rapidly, many new participants may enter the business, causing oversupply of product, declining margins, and possible bankruptcies.

The growth prospects of an industry also should be considered in a global context, particularly if a company has international exposure. Frequently, the growth prospects of an industry vary by country. For example, the soft drinks industry is declining in the United States but continues to achieve high growth in many emerging market countries.

Research and Development Expenses

The broad assessment of growth prospects is tempered by the third variable—the research and development (R&D) expenditures required to maintain or expand market position. Products with high-tech components can become dated and obsolete quickly. Therefore, although a company may be well situated in an industry, if it does not have the financial resources to maintain a technological lead or at least expend a sufficient amount of money to keep technologically current, its position is likely to deteriorate in the long run. In the short run, however, a company with R&D expenditures consistently below industry averages may produce above-average results because of expanded margins.

Evaluation of research and development is further complicated by the direction of technology. Successful companies not only must spend an adequate amount of resources on development, but they also must be correct in their assessment of the direction of the industry. Deployment of significant amounts of capital may not prevent a decline in credit quality if the capital is misdirected. For example, computer companies that persisted in devoting a high percentage of their capital expenditures to the mainframe component of their business suffered declines in credit quality as the mainframe business declined. In industries such as software and telecommunications, new technologies emerge frequently, and not all achieve market viability. A company that ties its product plans to the wrong technology loses competitive ground in addition to being unable to recover a substantial investment in R&D.

Competition

Competition is based on a variety of factors, with their relative importance varying by industry. Price is almost always a major competitive consideration, but product quality also affects the customers' decisions. For many consumer products it is difficult to measure product quality by objective standards. Brand name recognition and celebrity endorsements consequently shape perceptions of product quality. Companies also compete by striving to achieve advantages in distribution and by cultivating long-term relationships with customers.

Some companies are able to maintain strong competitive positions over extended periods through patents and trademarks. The flip side is that the expiration of a patent can lead to a major revenue loss. This is particularly pertinent for a pharmaceutical maker that will have to begin competing with generic drug producers once patent protection expires on a highly successful product. Another danger signal is heavy concentration of revenues at a small number of customers. In such a situation, a decision by a major customer to switch to another provider could deal a severe blow.

Increasingly, all forms of competition are waged on an international basis and are affected by fluctuations in relative currency values. Companies that fare well are those that compete successfully on a global basis and concentrate on the regions with the highest potential for growth. Consumers are largely indifferent to the country of origin of a product as long as the product is of high quality and reasonably priced. This fact is exemplified by the significant increase in the manufacture of automobiles and automobile parts in Mexico that are shipped to the United States.

Competition within an industry relates directly to the market structure of an industry and has implications for pricing flexibility. An unregulated monopoly is in an enviable position in that it can price its goods at a level that will maximize profits. Most industries encounter some free-market forces and must price their goods in relation to supply and demand, as well as the price charged for similar goods. In an oligopoly, a pricing leader is not uncommon. A concern arises when a small company is in an industry that is moving toward oligopoly. In this environment, the small company's costs of production may be higher than those of the industry leaders, and yet it may have to conform to the pricing of the industry leaders. In the extreme, a price war could force the smaller companies out of business. This situation has occurred in the automobile industry over many decades, first on a national and later on a global basis. Many U.S. producers either failed or merged with larger competitors as the field narrowed to the Big Three—General Motors, Ford Motor Company, and Chrysler. In addition to getting squeezed on costs and pricing, smaller automakers faced a disadvantage in producing fewer models, making them more sensitive to changes in consumer tastes than the industry leaders. Similarly, concentration in one region of the world became a handicap as the industry globalized. Recessions usually vary in severity from country to country, so global producers could reduce their vulnerability to economic downturns by spreading their sales across continents.

A concern also arises when there is overcapacity in the industry. Often overcapacity is accompanied by price wars. Generally, price wars result in an industry-wide financial deterioration as battles for market share are accompanied by declining profits or losses.

Sources of Supply

The market structure of an industry and its competitive forces have a direct impact on the fifth industry variable—sources of supply of major production components. A company that is not self-sufficient in its factors of production but is sufficiently powerful in its industry to pass along increased costs is in an enviable position.

Degree of Regulation

In a regulated monopoly such as electric power generation, pricing is determined by a government body. The intention is to prevent companies from extracting excess profits, yet to provide a fair rate of return on capital. That policy tends to promote stable earnings regardless of economic conditions. State regulatory commissions vary, however, in their responsiveness to requests for rate relief to offset increased costs.

Non-monopoly industries face regulation in such areas as labor practices, financial reporting, product safety, and environmental impact. The costs of complying with these regulations are often substantial and the ability to pass the costs on to customers varies by industry. Compliance with regulations that are stricter than in other countries may disadvantage companies relative to foreign-based competitors. Violating regulations can result in costly fines as well as reputational damage that may result in lost business.

Labor

The seventh industry factor requiring analysis is the labor situation. Is the industry heavily unionized? If so, what has been the historical incidence of strikes? What level of flexibility does management have to reduce the labor force? When do the current contracts expire, and what is the likelihood of timely settlements? The labor situation is also important in nonunionized companies, particularly those whose labor situation is tight. What has been the turnover of professionals and management in the firm? What is the probability of a firm's employees, such as highly skilled engineers, being hired by competing firms? What is the likelihood of union activity in nonunionized companies? Are the states in which unionization is a possibility right-to-work states and therefore more difficult to unionize? How much of a cost advantage do the nonunionized companies have over the unionized companies?

The more labor-intensive an industry, the more significance the labor situation assumes. This fact is evidenced by the domestic automobile industry, in

which overcapacity and high unionization have contributed to high fixed costs and cyclic record operating losses.

Occasionally, analysts concentrate on the per-hour wages of the labor force. Such an emphasis is misleading. An evaluation of the labor force should concentrate on work rules because work rules are more important in the overall efficiency of an organization than the wage rates. This is an important factor in the profitability of some automobile supply companies.

Accounting

One more industry factor to be considered is accounting. Does the industry have special accounting practices, such as those in the insurance industry or the electric utility industry? If so, an analyst should become familiar with industry practices before proceeding with a company analysis. Also important is whether a company is liberal or conservative in applying accounting rules. The norm of an industry should be ascertained and the analyst should analyze comparable figures.

Particular attention should be paid to companies that use an accounting system other than U.S. generally accepted accounting principles (GAAP). Reported results should be reconciled with those which would have been reported under U.S. GAAP. In addition, changes in GAAP should be scrutinized.

Care also should be taken when dealing with historical data. Frequently, companies adjust prior years' results to accommodate discontinued operations and changes in accounting. These adjustments can mask unfavorable trends. For example, companies that regularly dispose of underperforming segments and then highlight the more profitable continuing operations may be trying to hide poor management. To appreciate all trends fully, both the unadjusted and the adjusted results should be analyzed.

Accounting practices also demand attention when mergers and acquisitions occur. How much of pro-forma synergies are attributable to savings that are not yet realized but are allowed in pro-forma results? How much goodwill is generated by the combination? Are any contracts written up because the acquiring company believes that it can improve the historical performance of the company it acquired? A conscientious analyst will be aware of these accounting entries and determine whether they reflect a pro forma reality or, a too-optimistic assessment of future performance.

Event Risk

The final industry factor to consider is event risk. This term refers to a major discontinuity in a company's financial performance. It includes transactions that radically alter a company's capital structure, such as leveraged buyouts and takeovers that are heavily financed with debt. Event risk also comprises shocks such as natural disasters, environmental catastrophes, nationalizations, terrorist attacks, and revelations of accounting fraud.

Shocks can have severe credit impact, up to and including bankruptcy. As an example, during the course of June 2010 Moody's Investors Service lowered BP's credit rating all the way from Aa1 to A2. The two-stage downgrade reflected potential costs of containment, cleanup, litigation, and fines arising from the company's massive oil spill in the Gulf of Mexico. Shocks are unforeseeable by their nature, but to some extent it is possible to assess a company's probability of experiencing a shock.

FINANCIAL ANALYSIS

Having achieved an understanding of an industry, the analyst is ready to proceed with a financial analysis. The financial analysis should be conducted in three phases. The first phase consists of traditional ratio analysis for bonds. The second phase, generally associated with common stock research, consists of analyzing the components of a company's return on equity. The final phase considers such nonfinancial factors as management and foreign exposure and includes an analysis of the indenture.

Traditional Ratio Analysis

There are numerous ratios that can be calculated in applying traditional ratio analysis to bonds. Of these, the following eight will be discussed in this section:

- Pretax interest coverage
- Leverage
- Cash flow
- Net assets
- Intangibles
- Unfunded pension liabilities
- Age and condition of plant
- Working capital

These selected ratios are the ones with the widest degree of applicability. In analyzing a particular industry, however, other ratios assume significance and should be considered.

Pretax Interest Coverage

Generally, the first ratio calculated in credit analysis is pretax interest coverage. This ratio measures the number of times interest charges are covered on a pretax basis. Pretax interest coverage is calculated by dividing pretax income plus interest charges by total interest charges. The higher the coverage figure, the safer is the credit. If interest coverage is less than 1×, the company must borrow or use cash flow or proceeds from the sale of assets to meet its interest payments.

Generally, published coverage figures are pretax as opposed to after-tax because interest payments are a pretax expense. Although the pretax interest coverage ratio is useful, its utility is a function of the company's other fixed obligations. For example, if a company has other significant fixed obligations, such as rents or leases, a more appropriate coverage figure would include these other fixed obligations. An example of this is the retail industry, in which companies typically have significant lease obligations. A calculation of simple pretax interest coverage would be misleading in this case because fixed obligations other than interest are significant.

The analyst also should be aware of any contingent liabilities such as a company's guaranteeing another company's debt. Although the company being analyzed may never have to pay interest or principal on the guaranteed debt, the existence of the guarantee diminishes the quality of the pretax coverage. In addition, the quality of the guaranteed debt must be considered.

Once pretax interest coverage and fixed-charge coverage are calculated, it is necessary to analyze the ratios' absolute levels and the numbers relative to those of the industry. For example, pretax interest coverage for an electric utility of 3.0× is consistent with an A rating, whereas the same coverage for a drug company would indicate a lower rating.

Exhibit 43–2 shows the various key pretax interest coverage ratios reported by Standard & Poor's and how they are computed by that rating agency. The exhibit defines each measure used in a ratio and the formula.

Leverage

A second important ratio is leverage, which can be defined in several ways. The most common definition of *leverage* is long-term debt as a percent of total capitalization. The higher the level of debt, the higher is the percentage of operating income that must be used to meet fixed obligations. If a company is highly leveraged, the analyst also should look at its margin of safety. The *margin of safety* is defined as the percentage by which operating income could decline and still be sufficient to allow the company to meet its fixed obligations.

The traditional method of calculating leverage uses the company's capital structure as stated in the most recent balance sheet. A helpful supplement to the traditional ratio is the *market-adjusted debt ratio*. It uses debt as reported, but substitutes for stated shareholders' equity the market value of all outstanding shares.

One drawback to the traditional, book-value-based leverage ratio is that the accounting rules generally require physical assets to be recorded at historical cost. They may be written down to reflect impairment, but not written up to reflect increases in their economic value, unless they become involved in an acquisition. Furthermore, the accounting rules require immediate expensing, rather than capitalizing, of many outlays that create substantial long-run value. Examples include research and development, the creation of brand names, and the buildup of an effective sales organization. Consequently, the traditional ratio may overstate leverage by understating the economic value of the company's equity.

EXHIBIT 43–2

S&P Glossary of Terms and Formula for Key Ratios

Glossary

Pretax income from continuing operations: Net income from continuing operations before (1) special items, (2) minority interest, (3) gains or reacquisition of debt, plus income taxes.

Eight times rents: Gross rents paid multiplied by capitalization factor of eight.

Equity: Shareholders' equity (including preferred stock) plus minority interest.

Free operating cash flow: Funds from operations minus capital expenditures and minus (plus) the increase (decrease) in working capital (excluding changes in cash, marketable securities, and short-term debt).

Funds from operations (or funds flow): Net income from continuing operations plus depreciation, amortization, deferred income taxes, and other noncash items.

Gross interest: Gross interest incurred before subtracting (1) capitalized interest, (2) interest income.

Gross rents: Gross operating rents paid before sublease income.

Interest expense: Interest incurred minus capitalized interest.

Long-term debt: As reported, including capitalized lease obligations on the balance sheet.

Operating income: Sales minus cost of goods manufactured (before depreciation and amortization), selling, general and administrative, and research and development costs.

Total debt: Long-term debt plus current maturities, commercial paper, and other short-term borrowings.

Formulas for Key Ratios

$$\text{Pretax interest coverage} = \frac{\text{Pretax income from continuing operations} + \text{Interest expense}}{\text{Gross interest (before subtracting capitalized interest and interest income)}}$$

$$\text{Pretax interest coverage including rents} = \frac{\text{Pretax income from continuing operations} + \text{Interest expense} + \text{Gross rents}}{\text{Gross interest} + \text{Gross rents}}$$

$$\text{EBITDA interest coverage} = \frac{\text{Pretax income from continuing operations} + \text{Interest expense} + \text{Depreciation and amortization}}{\text{Gross interest}}$$

$$\text{Funds from operations (or funds flow) as a \% of total debt} = \frac{\text{Funds from operations}}{\text{Total debt}} \times 100$$

$$\text{Free operating cash flow as a \% of total debt} = \frac{\text{Free operating cash flow}}{\text{Total debt}} \times 100$$

(Continued)

EXHIBIT 43–2

S&P Glossary of Terms and Formula for Key Ratios (*Continued*)

Pretax return on permanent capital

$$= \frac{\text{Pretax income from continuing operations} + \text{Interest expense}}{\text{Sum of (1) the average of the beginning of year and end of year current maturities, long-term debt, noncurrent deferred taxes, minority interest, and shareholders' equity and (2) average short-term borrowings during year per footnotes to financial statements}} \times 100$$

$$\text{Operating income as a \% of sales} = \frac{\text{Operating income}}{\text{Sales}} \times 100$$

$$\text{Long-term debt as a \% of capitalization} = \frac{\text{Long-term debt}}{\text{Long-term debt} + \text{Equity}} \times 100$$

$$\text{Total debt as a \% of capitalization} + \text{short-term debt} = \frac{\text{Total debt}}{\text{Total debt} + \text{Equity}} \times 100$$

Total debt + 8 times rents as a % of capitalization + short-term debt + 8 times rents

$$= \frac{\text{Total debt} + 8 \text{ times gross rentals paid}}{\text{Total debt} + \text{Equity} + 8 \text{ times gross rentals paid}} \times 100$$

Source: "Adjusted Key U.S. Industrial Financial Ratios," *Standard & Poor's Credit Week*, September 20, 2000, pp. 39–44.

The market-adjusted version is a useful corrective, because under normal conditions, the stock market will reflect a disparity—whether positive or negative—between the book value and economic value of a company's assets. Analysts should bear in mind, however, that share prices can be highly volatile. As gauged by the company's stock market value, leverage may look considerably higher a month from now than today, with the change mainly reflecting a general drop in share prices rather than a fundamental decline in the company's earnings prospects.

Finance companies traditionally have been among the most highly leveraged companies. Debt-to-equity ratios of 10:1 are not unusual for *captive finance companies* that finance the sales of, and have debt guarantees from, parent companies engaged in manufacturing or retailing. For noncaptive companies, ratios of 5:1 to 7:1 are typical nowadays. Investors tolerate finance companies' high leverage because of the generally liquid nature of their assets. Loans, receivables, and other financial instruments ordinarily can be sold without substantial loss of face value if necessary to repay maturing debt. In contrast, industrial companies typically include large amounts of plant and equipment that cannot be disposed of so quickly. Therefore, book-value-based leverage of 5:1 or more would cause an industrial company to be viewed as highly speculative.

In addition to considering the absolute and relative levels of leverage of a company, the analyst should evaluate the debt itself. How much of the debt has a fixed-rate, and how much has a floating rate? A company with a high component of debt tied to the prime rate may find its margins being squeezed as interest rates rise if there is no compensating increase in the price of the firm's goods. Such a debt structure may be beneficial during certain phases of the interest-rate cycle, but it precludes a precise estimate of what interest charges for the year will be. In general, a company with a small percentage of floating-rate debt is preferable to a similarly leveraged company with a high percentage of floating-rate debt.

The maturity structure of the debt also should be evaluated. What is the percentage of debt that is coming due within the next five years? As this debt is refinanced, how will the company's embedded cost of debt be changed?

The existence of material operating leases can understate the leverage of a firm. Operating leases should be capitalized to give a true measure of leverage.

A company's bank lines often constitute a significant portion of its total debt. These lines should be analyzed closely in order to determine the flexibility afforded to the company. The lines should be evaluated in terms of undrawn capacity as well as security interests granted. In addition, the analyst should determine whether the line contains a "material adverse change" (MAC) clause under which the line could be withdrawn. For example, a company that has drawn down its bank lines completely and is in jeopardy of activating its MAC clause may have trouble refinancing any debt. In a similar manner, undrawn lines should be evaluated in terms of their capacity to replace commercial paper, if needed. In the event that a company's commercial paper rating is downgraded, the company's access to the commercial paper market may evaporate quickly. In this scenario, the company may be forced to draw on its bank lines to replace its maturing commercial paper. A company whose commercial paper is fully backed by bank lines is in a stronger position than one whose bank lines do not cover its outstanding commercial paper.

Exhibit 43–2 shows the key leverage ratios used by Standard & Poor's and the formula for calculating each ratio.

Cash Flow

A third important ratio is cash flow as a percent of total debt. *Cash flow* is often defined as net income from continuing operations plus depreciation, depletion, amortization, and deferred taxes. In calculating cash flow for credit analysis, the analyst also should subtract noncash contributions from subsidiaries. In essence, the analyst should be concerned with cash from operations. Any extraordinary sources or uses of funds should be excluded when determining the overall trend of cash-flow coverage. Cash dividends from subsidiaries also should be questioned in terms of their appropriateness (too high or too low relative to the subsidiary's earnings) and also in terms of the parent's control over the upstreaming of dividends. Is there a legal limit to the upstreamed dividends? If so, how close is the current level of dividends to the limit?

Net Assets

A fourth significant ratio is net assets to total debt, which gauges a company's ability to repay debt by liquidating assets to generate cash. This is not something companies do under normal circumstances; their ordinary practice is to refinance debt as it comes due or repay it from operating cash flow. Asset liquidation for debt repayment is most apt to occur when a company is under financial strain, when asset values are likely to be depressed. Therefore, analysts must be mindful that at the point at which liquidation value becomes relevant, it may differ significantly from the value currently reflected on the balance sheet and also from the present market value.

Discrepancies between book value and liquidation value arise from the inherently illiquid nature of many fixed assets. Consider a specialized piece of heavy equipment in a mine in a remote area. The balance sheet value associated with this asset is its purchase price less depreciation charges recorded since the equipment was acquired. Not reflected in that valuation are the costs of transporting the equipment to a buyer. Moreover, the depreciation charges, which were set at the time of the machinery's purchase, may not take into account the possibility of subsequent introduction of a competing, more cost-effective model, which would reduce the value of earlier-generation equipment.

To identify gaps between book value and liquidation value, analysts can obtain information on sales of comparable assets. In the energy sector, for example, widely reported sales of oil reserves provide dollars-per-barrel benchmarks. Acquisitions of retailing chains and restaurants similarly furnish useful estimates of current market value of comparable properties.

Even when such market-based data can be found, however, debt holders must be cautious about concluding that their principal will be fully covered in liquidation. For example, suppose that during a period of airline industry prosperity an airline sells bonds collateralized by planes. The prices then being paid for used aircraft may imply that the collateral's asset value comfortably exceeds the face amount of the bonds. The bonds may come due, however, when the notoriously cyclical airline business is in a downturn, making it difficult for the borrower to refinance the debt. Demand for used aircraft is likely to be minimal at that point, reducing the liquidation value of the collateral to much less than the bonds' face amount.

Takeovers, recapitalizations, and other restructurings increase the importance of asset coverage protection. Unfortunately for some bondholders, mergers or takeovers may decimate their asset coverage by adding layers of debt to the corporate structure that is senior to their holdings. While the analyst may find it difficult to predict takeovers, it is crucial to evaluate the degree of protection from takeovers and other restructurings that the bond indenture offers.

In extreme cases, the analyst must consider asset coverage in the case of bankruptcy. This is particularly important in the case of lease obligations because the debtor has the ability to reject leases in bankruptcy. In the case of lease rejections, the resulting asset protection may depend on a legal determination

of whether the underlying lease is a true lease or a financing arrangement. Even if the lease if determined to be a true lease, the determination of asset protection is further complicated by a determination of whether the lease relates to nonresidential real property or to personal property. The difference in security (i.e., recovery in a bankruptcy) is significant. Damages under a lease of nonresidential real property are limited to three years of lease payments. Damages under a lease of personal property are typically based on all amounts still due under the lease.

In addition to the major variables just discussed, the analyst also should consider several other financial variables, including intangibles, unfunded pension liabilities, the age and condition of the plant, and working capital adequacy.

Intangibles

Intangibles often represent a small portion of the asset side of a balance sheet. Occasionally, particularly with companies that have or have had an active acquisition program, intangibles can represent a significant portion of assets. In this case, the analyst should estimate the actual value of the intangibles and determine whether this value is in concert with a market valuation. A carrying value significantly higher than market value indicates a potential for a write-down of assets. The actual write-down may not occur until the company actually sells a subsidiary with which the intangibles are identified. However, the analyst should recognize the potential and adjust capitalization ratios accordingly.

Unfunded Pension Liabilities

Unfunded pension liabilities also can affect a credit decision. Although a fully funded pension is not necessary for a high credit assessment, a large unfunded pension liability that is 10% or more of net worth can be a negative. Of concern is the company with unfunded pension liabilities high enough to interfere with corporate planning.[2] For example, in the late 1980s, a steel company with high unfunded pension liabilities might have delayed or decided against closing an unprofitable plant because of the pension costs involved. The analyst also should be aware of a company's assumed rate of return on its pension funds and salary-increase assumptions. The higher the assumed rate of return, the lower the contribution a company must make to its pension fund, given a set of actuarial assumptions. Occasionally, a company having difficulty with its earnings will raise its actuarial assumption and thereby lower its pension contribution and increase earnings. The impact on earnings can be dramatic. In other cases, companies have attempted to "raid" the excess funds in an overfunded retirement plan to enhance earnings.

2. For a discussion of the impact of accounting for defined benefit pension plans on key financial measures (leverage, earnings, and cash flow) and a methodology to adjust these measures to reflect the true economic impact of pension plans, see David Zion and Bill Carcache, *The Magic of Pension Accounting: Part II*, Equity Research, Credit Suisse First Boston (October 15, 2003).

In periods of declining interest rates, the analyst also must consider the discount rate companies use to discount their future obligations. Companies generally use the yield of AA corporate bonds as a discount factor, a benchmark that has been criticized by market analysts.

Age and Condition of Plant

The age of a company's plant also should be estimated, if only to the extent that it differs dramatically from industry standards. A heavy industrial company with an average plant age well above that of its competitors is probably already paying for its aged plant through operating inefficiencies. In the longer term, however, the age of the plant is an indication of future capital expenditures for a more modern plant. In addition, underdepreciation of the plant significantly increases reported earnings.

The availability of information regarding the average age and condition of plants varies among companies. On the one hand, airline carriers readily provide the average age of their fleet and the money they will save as they replace older aircraft with more fuel-efficient aircraft that require fewer people in the cockpit. On the other hand, the average age of a plant compared with the industry average is not always available for some companies such as paper producers. Furthermore, companies with older plants generally emphasize the capital improvements that have been made to them over the years, which distort direct comparisons. In this case, it is helpful to read closely several years of management's explanation of operating results in the annual reports. Often this section will include mentions of above-average maintenance expense and machines that were out of service for a period of time for maintenance. Such comments indicate that the plants and machines may not be as efficient as portrayed initially.

Working Capital

A final variable in assessing a company's financial strength concerns the strength and liquidity of its working capital. *Working capital* is defined as current assets less current liabilities. Working capital is considered a primary measure of a company's financial flexibility. Other such measures include the current ratio (current assets divided by current liabilities) and the acid test (cash, marketable securities, and receivables divided by current liabilities). The stronger the company's liquidity measures, the better it can weather a downturn in business and cash flow.

In assessing this variable, the analyst should consider the normal working capital requirements of a company and industry. The components of working capital also should be analyzed. Although accounts receivable are considered to be liquid, an increase in the average days a receivable is outstanding may be an indication that a higher level of working capital is needed for the efficient running of the operation. Furthermore, companies frequently have account receivable financing, some with recourse provisions. In this scenario, comparisons among companies in the same industry may be distorted.

The state of contraction or expansion also should be considered in evaluating working capital needs. Automobile manufacturers typically need increased working capital in years when automobile sales increase.

Analysis of the Components of Return on Equity

Once the preceding financial analysis is complete, the bond analyst traditionally examines the earnings progression of the company and its historical return on equity (ROE). This section of analysis often receives less emphasis than the traditional ratio analysis. It is equally important, however, and demands equivalent emphasis. An analysis of earnings growth and ROE is vital in determining credit quality because it gives the analyst necessary insights into the components of ROE and indications of the sources of future growth. Equity analysts devote a major portion of their time to examining the components of ROE, and their work should be recognized as valuable resource material.

A basic approach to examining the components of ROE breaks down return on equity into four principal components: pretax margins, asset turnover, leverage, and one minus the tax rate.[3] These four variables multiplied together equal net income/stockholders' equity, or return on equity, as shown below:

$$\text{Net income/equity} = (\text{net pretax income/sales} + \text{operating pretax income/sales}) \times (\text{sales/assets}) \times (\text{assets/equity}) \times (1 - \text{tax rate})$$

The analyst should examine the progression of these four components of ROE for a minimum of five years and through at least one business cycle. The progression of each variable should be compared with the progression of the same variables for the industry, and deviations from industry standards should be further analyzed. For example, perhaps two companies have similar ROEs, but one company is employing a higher level of leverage to achieve its results, whereas the other company has a higher asset-turnover rate. Since the degree of leverage is largely a management decision, the analyst should focus on asset turnover. Why have sales for the former company turned down? Is this downturn a result of a general slowdown in the industry, or is it that assets have been expanded rapidly, and the company is in the process of absorbing these new assets? Conversely, a relatively high rise in asset-turnover rate may indicate a need for more capital. If this is the case, how will the company finance this growth, and what effect will the financing have on the firm's embedded cost of capital?

The analyst should not expect similar components of ROE for all companies in a particular industry. Deviations from industry norms are often indications of management philosophy. For example, one company may emphasize asset turnover, and another company in the same industry may emphasize profit margin. As in any financial analysis, the trend of the components is as important as the absolute levels.

3. The formula was first presented in Jerome B. Cohen, Edward D. Zinbarg, and Arthur Zeikel, *Investment Analysis and Portfolio Management* (Homewood, IL: Richard D. Irwin, 1977).

Nonfinancial Factors

After the traditional bond analysis is completed, the analyst should consider some nonfinancial factors that might modify the evaluation of the company. Among these factors are the degree of foreign exposure, the quality of management, and ownership. The amount of foreign exposure should be ascertainable from the annual report. Sometimes, however, specific country exposure is less clear because the annual report often lists foreign exposure by broad geographic divisions. If there is concern that a major portion of revenue and income is derived from potentially unstable areas, the analyst should carefully consider the total revenue and income derived from the area and the assets committed. Further consideration should be given to available corporate alternatives should nationalization of assets occur. Additionally, the degree of currency exposure should be determined. If currency fluctuations are significant, has management hedged its exposure?

The internationalization of the bond markets and the ability of countries to issue debt in other countries highlight the importance of understanding the effect of currency risks. For example, many Mexican companies issued U.S. dollar–denominated debt in the early 1990s. This issuance had a positive impact on the financials of these Mexican companies because of the generally lower interest rates available in the United States relative to Mexico. However, when the peso was devalued significantly in December 1994, the ability of some of these companies to meet their U.S. dollar–denominated obligations was questioned. Of particular concern were the companies whose revenues were largely denominated in pesos but whose interest expense was denominated in U.S. dollars.

The quality and depth of management are more difficult to evaluate. The best way to evaluate management is to spend time with management, if possible. Earnings progress at the firm is a good indication of the quality of management. Negative aspects would include a firm founded and headed by one person who is approaching retirement and has made no plan for succession. Equally negative is the firm that has had numerous changes of management and philosophy. On the other hand, excessive stability is not always desirable. In discussing the factors it considers in assigning a credit rating, Moody's Investors Service notes the following regarding the quality of management:

> Although difficult to quantify, management quality is one of the most important factors supporting an issuer's credit strength. When the unexpected occurs, it is a management's ability to react appropriately that will sustain the company's performance.[4]

In assessing management quality, the analysts at Moody's, for example, try to understand the business strategies and policies formulated by management. Following are factors that are considered: (1) strategic direction, (2) financial

4. "Industrial Company Rating Methodology," *Moody's Investors Services: Global Credit Research*, July 1998, p. 6.

philosophy, (3) conservatism, (4) track record, (5) succession planning, and (6) control systems.

In recent years, focus has been on the corporate governance of the firm and the role of the board of directors. The bylaws are the rules of governance for the corporation. The bylaws define the rights and obligations of officers, members of the board of directors, and shareholders. Several firms have developed services that assess corporate governance. One type of service provides confidential assessment of the relative strength of a firm's corporate governance practices. The customer for this service is a corporation seeking external evaluations of its current practice. The second is a service that rates (or scores) the corporate governance mechanisms of companies. Generally, these ratings are made public at the option of the company requesting an evaluation.

Analysts should also consider the ownership of a company. If a single family or small group of investors holds a controlling interest, the company may tend to be overly conservative in its response to changes in its markets. Owners also should be judged in terms of whether they are strategic or financial. Often financial buyers invest for the short to intermediate term, hoping to sell their positions (or the entire company) at a profit. If such a sale involves a leveraged buyout, the credit quality of the bonds is lowered, sometimes dramatically.

COMBINING FINANCIAL AND NONFINANCIAL ANALYSIS

The ultimate credit judgment on a company must consider both its financial risk profile and its business risk profile. Strength in one aspect of credit quality may be offset by weakness in the other. Exhibit 43–3 illustrates one approach to integrating the two modes of analysis.

Standard & Poor's employs a matrix of six levels of business risk, from "excellent" to "vulnerable," and six levels of financial risk, from "minimal" to "highly leveraged." The table shows the midpoint of the range of ratings that may be assigned to a company within a given cell. The actual rating ordinarily will be within one notch of that rating. For example, in most cases a company with a "satisfactory" business risk profile and an "intermediate" financial risk profile will be rated in the range of BBB+ to BBB–.

Certain cells, such as "excellent" business risk profile/"highly leveraged" financial risk profile, are blank. This is because such combinations are extremely improbable. For some companies, overarching risks such as major litigation and balance-sheet-straining acquisitions fall outside the matrix. Finally, the matrix excludes ratings lower than CCC+ because by definition, companies in those categories reflect an acute vulnerability or impending crisis.

Specific obligations may be rated higher than the company rating, based on security, or lower than the company rating, based on subordination within the capital structure. Subordination includes *structural subordination*, whereby servicing of a holding company's debt depends on receiving dividends from

EXHIBIT 43–3

Business and Financial Risk Profile Matrix

Business Risk Profile	Financial Risk Profile					
	Minimal	Modest	Intermediate	Significant	Aggressive	Highly Leveraged
Excellent	AAA	AA	A	A–	BBB	—
Strong	AA	A	A–	BBB	BB	BB–
Satisfactory	A–	BBB+	BBB	BB+	BB-	B+
Fair	—	BBB–	BB+	BB	BB–	B
Weak	—	—	BB	BB–	B+	B–
Vulnerable	—	—	—	B+	B	CCC+

These rating outcomes are shown for guidance purposes only. Actual rating should be within one notch of indicated rating outcomes.

subsidiaries. By law, dividends can be paid only after the subsidiaries' own debt has been serviced.

Exhibit 43–4 provides a key to the classifications of companies within the six financial risk profile categories. For example, a company with funds flow from operations to debt of 45% to 60%, debt/earnings before interest, taxes, depreciation, and amortization (EBITDA) of 1.5 to 2×, and debt/capital of 25% to 35% is deemed to have "modest" financial risk. S&P characterizes these benchmark ratios as guidelines rather than absolute rules. For instance, a company with very stable financial ratios may qualify for a particular financial risk category despite a somewhat lower FFO/debt percentage or a higher debt/capital percentage than shown in the exhibit. Electric utilities benefit from this leeway because of their demonstrated superiority in access to capital, their liquidity, and their effective management of capital programs and maturity schedules.

EXHIBIT 43–4

Financial Risk Indicative Ratios (Corporate)

	FFO/Debt (%)	Debt/EBITDA (x)	Debt/Capital (%)
Minimal	Greater than 60	Less than 1.5	Less than 25
Modest	45–60	1.5–2	25–35
Intermediate	30–45	2–3	35–45
Significant	20–30	3–4	45–50
Aggressive	12–20	4–5	50–60
Highly Leveraged	Less than 12	Greater than 5	Greater than 60

INDENTURE PROVISIONS

An *indenture* is a contract that defines the legal rights and obligations of the issuer and the bondholders, represented through the trustee, with respect to a bond issue. The indenture establishes fundamental rules for three primary investor concerns: (1) payments by the issuer to bondholders; (2) limits on the kinds of issuer behavior that may harm bondholders' prospects for repayment; and (3) the enforcement mechanisms available to bondholders if issuers do not fulfill their obligations.

First, the indenture and the related note that represents the debt enshrine a bondholder's individual right to the timely payment of principal and interest. The bond may also be subject to special pricing and redemption provisions, such as a ratings-based coupon step-up, a call schedule, a make-whole redemption, a sinking fund, or a maintenance and replacement fund. These payment provisions are discussed in Chapter 12.

Second, the indenture will contain provisions called *covenants* that attempt to limit some issuer behavior that could increase credit risk. For example, if an issuer doubles its amount of outstanding debt in order to pay dividends to shareholders while neglecting reinvestment in its business, then bondholders will face a greater risk of a payment default on their bonds. A strong Debt covenant or Restricted Payments covenant could limit this kind of recapitalization event. Indenture analysis is principally focused on restrictive covenants not only to help evaluate contractual protections against risky behavior by issuers, but also to consider the upside possibility of a consent solicitation or a premium tender for their bonds if the issuer wants to take actions that otherwise would be restricted by the bond covenants. Covenant protections can have important market pricing implications, especially in the leveraged-buyout (LBO) context. When the Texas power company TXU Corp. was acquired in 2007, it had significant bonds outstanding at three different legal entities. The TXU holding company bonds had very weak covenant protections and remained outstanding and traded well below par for years after the LBO, while the TXU Energy subsidiary bonds had stronger covenant protections that would have impeded the optimal LBO financing, and so they were redeemed at a premium. The value of a third set of bonds was relatively protected because they had been issued by a different, state-regulated subsidiary with limits on its ability to borrow.

Covenant protections can vary enormously even among bonds of the same issuer, but they can generally be described as being investment-grade or high-yield type covenants. Some industry groups such as real estate investment trusts (REITs) and finance companies have special covenant features, as explained below. Bear in mind that covenants vary over time as investors become more or less sensitive to event risk and the view of what is "market" practice changes. For example, Change of Control puts and secured debt restrictions became very important for investment-grade bond investors following the 1988 LBO of RJR Nabisco, but then generally waned over the next two decades, until the buyout boom of the mid-2000s and resulting bondholder losses resurrected these kinds of protections.

Enforcement is the third primary concern. If there is a *default* under the indenture, then the enforcement of bondholder rights is handled according to detailed rules that are generally similar among all corporate indentures. Generally, if there is *payment default* because a principal or interest payment is not made on time, then the trustee may act on its own to sue for payment, although an individual bondholder can also sue for payment. If there is a *covenant default,* such as selling an asset in violation of an Asset Sales covenant, then enforcement could occur in several ways. The issuer might realize its mistake and attempt to *cure,* or remedy, the breach if possible. The issuer might ask bondholders for permission in a *consent solicitation* for a *waiver* from having to comply with the indenture provision or for an *amendment* to the indenture so that the covenant is changed. Bondholders or the trustee might become aware of a default and formally give notice of a default to try to *accelerate* the bonds for early payment. Sometimes, the issuer, trustee, and bondholders might disagree about the meaning of an indenture covenant and litigate the matter. For example, when Tyco International split its businesses into three separate, publicly traded companies, bondholders sued to stop the transaction based on a violation of the Mergers covenant, and Tyco paid to settle the litigation. Typically, either the trustee or 25% of bondholders must act in order to declare a default and attempt to accelerate the bonds.

Bond indentures should be considered in light of the covenants in bank credit agreements. Frequently, loan covenants can be more restrictive than bond covenants. In particular, credit agreements often contain *maintenance covenants* that require the borrower to maintain a certain level of consolidated net worth, a ratio of total debt to cash flow, or some other financial metrics that serve as a proxy for the creditworthiness of the borrower. If a maintenance covenant is breached, then the lenders can seek to accelerate. Bondholders sometimes hope that the more restrictive bank credit agreements will provide some aura of protection to bondholders, but investors should be cautious about this idea. Borrowers often ask lenders for waivers and amendments, and in recent years there are numerous examples in which some market participants took credit views based on expected covenant breaches that turned out to be incorrect, such as when MGM Mirage (Resorts) obtained a series of amendments from its lenders in 2009 that involved pledging additional collateral. Similarly, some analysts expected Clear Channel to face insolvency based on noncompliance with its leveraged-based maintenance covenant in 2009, but this view was based on a misunderstanding of the credit agreement definitions.

Note that the prospectus or offering memorandum for a bond will contain a description of the covenants, but it is the indenture that controls as the legally binding contract, and so the indenture should be used for covenant analysis. The indenture of a U.S. issuer usually can be obtained from the SEC's EDGAR website if the issuer is a public company or otherwise files with the SEC. Alternately, the indenture may be obtained from the trustee who is listed in the prospectus or sometimes directly from the issuer.

Outlined below are the most common indenture covenants, and how they vary for investment-grade versus high-yield bonds. Following that is an explanation of some special industry and bond types. Bear in mind that covenants work together as a kind of "system" where one corporate action can implicate multiple indenture provisions.

Typical Bond Covenants

Guarantees/Future Guarantors Covenant

A bond is primarily the obligation of the issuer. Often the issuer is a holding company that relies on its own subsidiaries to upstream cash for the issuer to make payments to bondholders. If the issuer fails to make a payment, then bondholders may want to make a claim for payment against the subsidiaries that hold the operating assets. This is possible if there are *subsidiary guarantees* by which the issuer's subsidiaries promise to pay interest and principal if the issuer does not. A bond may have subsidiary guarantees when it is issued, or a *Future Guarantors covenant* may require subsidiaries to provide guarantees in the future. Guarantees are an important determinant of recoveries in bankruptcy, especially when there may be significant debt, trade claims, or other liabilities against subsidiaries. A guarantee can put the bondholders' claims on an equal footing with other claims against subsidiaries.

Investment-grade bonds usually do not have subsidiary guarantees, while high-yield bonds typically are offered with these guarantees.

Debt Covenant

The *Debt covenant* limits the amount of additional borrowings by the issuer. A Debt covenant has become rare among investment-grade bonds, but is customary for high-yield issues. The typical version says that the issuer and its subsidiaries generally cannot incur debt unless a *Ratio test* is met, which typically requires meeting a pro forma 2× EBIDTA: interest expense coverage ratio or a maximum debt: EBITDA leverage ratio. However, even when the Ratio test cannot be met, certain types of *Permitted Debt* are allowed. Permitted Debt includes specific carveouts such as for a set amount of credit facilities, project and acquisition financing, and a general purpose debt basket. Generally, a Debt covenant is designed to allow an issuer to borrow more money when its EBITDA and total asset base are increasing. The risk to bondholders is that the new debt remains even if financial results decline, because the Debt covenant is not a maintenance covenant.

Importantly, for the Debt covenant and other restrictive covenants, investors must confirm which entities in the capital structure must obey the covenants. Ideally, the issuer and all its subsidiaries would be subject to the covenants, but many indentures exempt so-called unrestricted subsidiaries.

Subsidiary Debt Covenant

Investment-grade bonds occasionally have a *Subsidiary Debt covenant* that is intended to limit the amount of money that can be borrowed by subsidiaries, and therefore reduce the risk of structural subordination.

Negative Pledge/Liens Covenant

Bondholders generally do not want other debt to be secured ahead of or alongside their bonds, because secured debt will recover ahead of unsecured debt in bankruptcy. This concern is addressed by one of two similar provisions that have an important substantive difference. A *Negative Pledge covenant* is used for almost all unsecured bonds and generally requires that if some other debt becomes secured, then the bonds must be equally and ratably secured. The Negative Pledge for an investment-grade bond will typically only restrict pledging some subset of the issuer's total assets (for example, manufacturing plants), allow exceptions to finance capital expenditures and asset acquisitions, and have a *general secured debt carveout* equal to 10% to 15% of a balance sheet metric such as consolidated net tangible assets or stockholders' equity. For a high-yield bond, the covenant will typically apply to all of the issuer's assets, but a lengthy list of *Permitted Liens* will have carveouts matched to particular items of Permitted Debt and other exceptions.

In comparison, a secured bond should have a true *Liens covenant,* which restricts securing other debt and does not give the issuer the option to secure new debt by ratably securing the existing bonds, but would still allow some Permitted Liens.

Sale/Leaseback Covenant

A *Sale/Leaseback covenant* is standard for investment-grade bonds and is especially important when there is significant credit support from owned manufacturing facilities or high value real estate, such as department stores with owned locations. If a company sells real estate and then takes back a lease on that property, the bondholder is harmed twice: first, as there would be fewer assets to recover against in bankruptcy, and second, as the issuer will have committed itself to future lease payments. Therefore, the covenant usually blocks a sale/leaseback transaction unless it is used to finance a new location, or the proceeds of the sale are used to repay long-term debt or acquire new assets. This covenant has been fading from usage in high-yield bonds, in part because the sale would be addressed by the Asset Sales covenant of a high-yield bond, while aspects of the lease would be addressed by the Debt and Liens covenant.

Restricted Payments Covenant

A *Restricted Payments covenant* primarily limits the amount of dividends that can be paid to stockholders. While these dividend restrictions might occasionally appear in investment-grade bond issues, they are now generally restricted to

high-yield bonds. Typically, 50% of the issuer's net income can be paid to stockholders, on the theory that the other half of profits should be reinvested in the business or used to pay down debt. Paying dividends based on net income is also usually conditioned upon meeting the pro forma Ratio test of the Debt covenant. This same Restricted Payments covenant will also generally limit stock purchases, repaying subordinated debt before its maturity, and making so-called restricted investments in entities such as joint ventures that might not be obligated to obey the indenture covenants.

Asset Sales Covenant

The Asset Sales covenant is rare for investment-grade bonds but standard for high-yield bonds. The covenant does not prevent asset sales, but generally requires that the proceeds of a sale be used to acquire new assets or repay debt that is secured or otherwise effectively senior to the bonds. If that is not done, then the issuer usually must offer to buy back the bonds at par within a year.

Mergers Covenant

The *Mergers covenant,* also known as the successor obligor provision, is designed to ensure a degree of continuity between the bond debt and the issuer's assets that support the debt. If the issuer merges with another company or transfers "substantially all" of its assets to another company, then the bond obligation must remain with the merged company or bulk of the assets. Otherwise, investment-grade bondholders could be left holding bonds of a mere shell company that has sold off its assets, because an investment-grade bond usually does not have an Asset Sales covenant.

High-yield bonds have a similar Mergers covenant, but their version would generally require meeting the Debt covenant's Ratio test as a condition to the merger or asset transfer.

Change of Control Covenant

The *Change of Control covenant* is nearly universal for high-yield bonds and allows bondholders to put bonds back to the issuer at 101% upon a defined Change of Control. This covenant is currently common for nonfinancial investment-grade bonds, but with the additional requirement that the bonds become rated below investment-grade. The Change of Control definition may include one or more triggers such as: (1) a sale of substantially all assets; (2) the acquisition of more than half of the issuer's voting stock by a third party; (3) a merger with another company; (4) a liquidation of the company; and (5) a hostile change in the board of directors. The Change of Control put can be blunt protection against the risk of credit-damaging leverage in an LBO, a chance to assess the new ownership of the issuer, or a simple 101% put opportunity for a bond trading below par.

Special Covenants and Situations

Some industries and special situations have bond covenants that vary from the common pattern and we outline these below.

Real Estate Investment Trusts

REITs are almost always investment-grade issuers, and their covenants have a great degree of similarity to each other. The REIT indenture usually has one or more maintenance covenants based on levels of secured debt, unsecured debt, and interest coverage.

Utilities

Utilities tend to be investment-grade issuers yet have traditionally issued secured debt, often under the title of First Mortgage Bonds with indentures that have been used for decades, and sometimes feature maintenance and replacement funds and sinking funds. These secured bonds may limit the amount of additional debt that may be issued under the mortgage to a certain percentage of net property. Today, many utilities issue bonds with limited covenants that look like those of other investment-grade issuers, with only a standard make-whole redemption option. However, investors have some comfort that state utility regulations may effectively limit the leverage of these companies.

Finance Companies

Finance companies are usually investment-grade issuers and have less complex covenants than in the past. A negative pledge type Liens covenant is common, and if the issuer is a finance subsidiary of an operating company, such as GE Capital is a business of General Electric, then the parent may have a support guarantee in which the parent promises to invest in the finance subsidiary for it to maintain a certain net worth or other credit metric.

Banks and Insurance Companies

The holding companies for banks and insurance companies are typically rated investment-grade and their bonds will have a limited Liens covenant that restricts pledging shares of major subsidiaries and perhaps a limited kind of Asset Sales covenant that restricts selling significant minority stakes in major subsidiaries. The regulated subsidiaries may issue their own, higher-rated debt, in which the covenants are often less important because state and federal laws practically limit borrowing by regulated subsidiaries.

Split-Rated Issuers

Bonds issued with one investment-grade rating and one high-yield rating often have investment-grade covenants, but perhaps with the addition of a strong Future Guarantors covenant or a limited Restricted Payments covenant that controls dividend payments.

Secured High-Yield Bonds

Traditionally, bank loans were secured and bonds were not. This began to change significantly in the 2000s as bank lenders became comfortable with the idea of allowing bonds to be sold with second liens that would recover behind the bank loans. In 2010 over one-fourth of U.S. high-yield bonds were sold with some collateral protection, and both first and second liens are now common. These bonds are often subject to an *intercreditor agreement* that affirms the primacy of the lenders' liens and limits somewhat the arguments that bondholders can make in bankruptcy.

Private Bonds

So-called private bonds are usually small offerings that are sold to just a handful of institutions, tend not to trade frequently, and are generally not covered by research or media outlets. These bonds can often be more heavily negotiated and include loan-like maintenance covenants.

UTILITIES

Historically, utilities have been regulated monopolies. These companies generally operate with a high degree of financial leverage and low fixed-charge coverage (relative to industrial companies). These financial parameters have been accepted historically by investors owing to the regulation of the industry and the belief that there is minimal, if any, bankruptcy risk in those securities because of the essential services they provide.

The changing structure of the electric utility industry brought about by significant investment in nuclear generating units and their inherent risk, as well as the transition to deregulation, has changed this belief. Initially, the faltering financial position of General Public Utilities precipitated by the Three Mile Island nuclear accident and the regulatory delays in making a decision regarding the units highlighted the default risk that exists in the industry. Subsequently, the defaults of several Washington Public Power Supply System issues, the restructuring of Tucson Electric Company, and the bankruptcies of Public Service Company of New Hampshire and El Paso Electric Company and the transition to deregulation reemphasized the default risk. In addition, the industry is faced with the acid rain issue and increased uncertainty in construction costs and growth rates.

Segments within the Utility Industry

There are three major segments within the utility industry: electric companies, gas companies, and telephone companies. This chapter will deal primarily with electric utilities. Many companies are involved in both electric and gas service, so analysis requires a working knowledge of both businesses. A working knowledge of the different facets of the electric utility industry is also required as traditional electric

utilities diverge in their strategies, with some companies emphasizing transmission and distribution exclusively while other companies emphasize generation.

Nonfinancial Factors

Although financial factors are important in analyzing any company, nonfinancial factors are particularly important in the electric utility industry and may alter a credit assessment. The following nonfinancial factors are of particular importance to the utility industry: (1) regulation, (2) source of the company's energy, (3) growth and stability of the company's territory, (4) capital structure, (5) degree of activity in international and nonutility investments, and (6) competitive position.

To reflect the importance of nonfinancial factors, S&P utilizes a 10-point business risk assessment. In June 2004 S&P assigned new business profile scores to refine its assessment of relative risk among the utility and power companies. At that point the rating agency also divided the group into subsectors to allow more in-depth statistical analysis of the distribution of its ratings and its rating changes. The subsectors are Transmission and Distribution—Water, Gas, and Electric; Transmission Only—Electric, Gas, and Other; Integrated Electric, Gas, and Combination Utilities; Diversified Energy and Diversified Non-Energy; and Energy Merchant/Developers/Trading and Marketing.

Regulation

The utility industry includes both regulated and unregulated entities. In some cases, the two types coexist as subsidiaries within a single corporate structure. Power generation has been deregulated in some states, with merchant power companies selling electricity at competitive rates, but remains regulated in others. The transmission segment remains highly regulated. Retail distribution is deregulated, with consumers free to choose their providers based on such factor as price and quality of service.

For regulated entities, regulation is perhaps the most important credit analysis variable. Regulators, operating mainly at the state level, largely determine how much profit these businesses earn and retain. If a company has regulated operations in more than one state, the analyst should weight the evaluation of the regulatory environment by the revenues generated in each state. Evaluating regulatory commissions is a dynamic process.

The evaluation of regulatory commissions is a dynamic process. The composition of commissions changes because of retirements, appointments, and elections. The implications of personnel changes are not clear until decisions are made. For example, it is not always the case that elected commissioners are pro-consumer and appointments by a conservative governor are pro-business. Several brokerage firms can assist in evaluations of commissions.

In addition, the Federal Energy Regulatory Commission (FERC) regulates interstate operations and the sale of wholesale power. Currently, FERC regulation

is considered to be somewhat more favorable than that of the average state regulatory commission.

Utilities that are constructing or operating nuclear reactors are also subject to the regulation of the Nuclear Regulatory Commission (NRC). The NRC has broad regulatory and supervisory jurisdiction over the construction and operation of nuclear reactors. Importantly, the NRC approves licensing of nuclear reactors, as well as the transfer of licenses.

Regulation is best quantified by recent rate decisions and the trend of these decisions. Although a company being analyzed may not have had a recent rate case, the commission's decisions for other companies operating within the state may be used as a proxy. Regulatory commissions are either appointed or elected. In either case, the political atmosphere can have a dramatic effect on the trend of decisions.

The regulators determine innumerable issues in a rate decision, although analysts often mistakenly focus only on the allowed rate of return on equity or the percentage of request granted. For example, a commission might rule that an electric utility must reduce rates by 10%. However, if the commission allows the utility to accelerate its depreciation, the negative effect on the cash flow of the company from the rate reduction may be largely offset, particularly if the company had been or was expected to exceed its allowed ROE. The commissions also determine how much of construction work in progress (CWIP) is allowed into the rate base. A company may appear to have a favorable allowed ROE but be hurt by the fact that only a small portion of the company's capital is permitted to earn that return, and the CWIP earns nothing. Allowance of CWIP in the rate base was of critical importance during the 1980s because of the high construction budgets for nuclear generating plants and the length of time these plants were under construction. Some companies have had more than half their capital in CWIP that was not permitted to earn a return.

The importance of whether CWIP is allowed in the rate base is highlighted by the financial distress and January 1988 bankruptcy filing of Public Service Company of New Hampshire (PSNH). PSNH's Seabrook Nuclear Unit I was virtually complete in 1986. However, licensing delays and New Hampshire's statutory prohibition of CWIP in the rate base were major contributing factors in the bankruptcy filing.

In addition, regulators have a high degree of control over the cash flow of a company through the allowance or disallowance of accounting practices and the speed with which decisions are made on cases.

Source of the Company's Energy

The source of the company's energy is a second important variable, with the impact on fuel cost being especially important for merchant generators. Each fuel must be evaluated in the context of the overall cost of operating a plant. For many years, nuclear generation was out of favor because of extensive licensing requirements, high capital costs, and heavy decommissioning expenses. Companies with

large dependence on nuclear power were viewed less favorably than those with natural gas or coal units. More recently, nuclear-based generation companies have gained popularity among investors as they have written down their capital costs, while coal has suffered from escalating pollution concerns and the cost of oil and natural gas has risen. Additionally, in the mid 2000s, a number of nuclear-powered utilities were successful in their requests for 20-year license renewals.

Growth and Stability of the Company's Territory

The energy-source variable relates to a third variable—the growth and stability of the company's territory. Although above-average growth is viewed positively in an industrial company, above-average growth gets mixed reviews with respect to an electric utility. An electric utility with above-average growth may face construction earlier than its competitors depending on the supply/demand balance and regulation in its service territory.

Slow growth is not necessarily positive if it places a utility in a position of excess capacity. The increase in cogeneration and the mergers executed in order to better match supply and demand can place a utility at risk. This can result if utility A is selling power to utility B. If the expiration of the contract coincides with utility B's ability to purchase power for less and results in utility B's nonrenewal of the contract, utility A may be negatively affected unless it can sell the power to a third utility. The issue of growth has been complicated by deregulation and the requirement in many states for disaggregation of generation from transmission and distribution, as well as the requirement that customers be allowed to choose their supplier. In this new era, utilities engaged in generation must be able to match supply and demand for power.

Corporate Structure

A fourth variable, whether or not a company is a subsidiary of a holding company, also should be considered. Holding-company status permits nonutility subsidiaries, but these subsidiaries (even if successful) will not necessarily improve the overall credit quality of the company. This depends on the regulatory atmosphere. Furthermore, when there are several electric utility subsidiaries, the parent is more likely to give relatively large equity infusions to the relatively weak subsidiaries. The stronger subsidiary may have to support the other subsidiaries. Finally, holding companies should be analyzed in terms of consolidated debt. Although a particular subsidiary may have relatively strong financial parameters, off-balance-sheet financing may lower the overall assessment.

Competitive Position

A final nonfinancial factor is the competitive position of a utility. An electric utility with a comparatively low rate structure is generally in a stronger position politically to request rate increases or to request a rate freeze than one with rates higher than national averages and particularly one with rates higher than regional averages.

The competitive position of an electric utility is increasingly important as customer choice increases. Companies with high overall rates, and particularly those with high commercial rates, may find themselves losing customers as access to transmission and distribution lines increases.

Financial Analysis

The changing competitive nature of the electric industry resulting from deregulation requires that the traditional evaluation of an electric utility be modified. Although historic ratio analysis still should be conducted, an electric company also should be evaluated in the context of its new competitive situation. Is new generation being constructed in its territory that produces energy at a lower cost than the established generation? How does the company plan to expend its excess cash flow? In an era of consolidation, will the company be acquired or be an acquirer? Will the company remain in generation or sell its generation and deal solely with transmission and distribution? Location is also important. Some merchant power plants have been constructed too far from the power grid to succeed.

The following major financial ratios should be considered in analyzing an electric utility: (1) leverage, (2) pretax interest coverage, (3) cash-flow/capital expenditures, and (4) cash flow/capital.

Leverage

In calculating the debt leverage of an electric utility, long-term debt/capitalization is standard. However, the amount of short-term debt also should be considered because this is generally variable-rate debt. A high proportion of short-term debt also may indicate the possibility of the near-term issuance of long-term bonds. In addition, several companies guarantee the debt of subsidiaries (regulated or nonregulated). The extent of these guarantees should be considered in calculating leverage.

Fixed-charge coverage for the electric utilities is low relative to coverage for industrial companies. This is accepted by investors because of the stability of the industry. However, emphasis should be placed not only on the exact coverage figures but also on the trend and quality of the coverage.

A third important ratio is net cash-flow/capital expendures. This ratio should be approximated for three years (the typical electric company's construction forecast). The absolute level, as well as the trend of this ratio, gives important insights into the trend of other financial parameters. An improving trend indicates that construction spending probably is moderating, whereas a low net cash flow/spending ratio may indicate inadequate rates being approved by the commissions and a heavy construction budget. Estimates for construction spending are published in the company's annual reports. Although these are subject to revision, the time involved in building generation makes these forecasts reasonably reliable. In calculating cash flow, the standard definition outlined earlier

should be followed. However, allowance for funds used during construction (AFUDC) also should be subtracted.

FINANCE COMPANIES

Finance companies are essentially financial intermediaries. Their function is to purchase funds from public and private sources and to lend them to consumers and other borrowers of funds. Finance companies earn income by maintaining a positive spread between what the funds cost and the interest rate charged to customers. The finance industry is highly fragmented in terms of type of lending and type of ownership. This section will briefly outline the major sectors in the industry and then discuss the principal ratios and other key variables used in the analysis of finance companies.

Segments within the Finance Industry

The finance industry can be segmented by type of business and ownership. Finance companies lend in numerous ways in order to accommodate the diverse financial needs of the economy. Five of the major lending categories are (1) sales finance, (2) commercial lending, (3) wholesale or dealer finance, (4) consumer lending, and (5) leasing. Most often companies are engaged in several of these lines rather than one line exclusively. Sales finance is the purchase of third-party contracts that cover goods or services sold on a credit basis. In most cases, the sales finance company receives an interest in the goods or services sold. Commercial finance is also generally on a secured basis. However, in this type of financing, the security is most often the borrower's accounts receivable. In factoring, another type of commercial lending, the finance company actually purchases the receivables of the company and assumes the credit risk of the receivables.

Dealer or wholesaler finance is the lending of funds to finance inventory. This type of financing is secured by the financed inventory and is short term in nature. Leasing, on the other hand, is intermediate- to long-term lending—the lessor owns the equipment, finances the lessee's use of it, and generally retains the tax benefits related to the ownership.

Consumer lending historically has involved short-term, unsecured loans of relatively small amounts to individual borrowers. In part because of the more lenient bankruptcy rules and higher default rates on consumer loans, consumer finance companies have dramatically expanded the percentage of their loans for second mortgages. The lower rate charged to individuals for this type of loan is offset by the security and lower default risk of the loan.

There are numerous other types of lending in addition to those just described. Among these are real estate lending and export/import financing.

The ownership of a finance company can significantly affect evaluation of the company. In some instances, ownership is the most important variable in the analysis.

There are three major types of ownership of finance companies: (1) captives, (2) wholly owned, and (3) independents.

Captive finance companies, such as Ford Motor Credit, are owned by the parent corporation and are engaged solely or primarily in the financing of the parent's goods or services. Generally, maintenance agreements exist between the parent and the captive finance company under which the parent agrees to maintain one or more of the finance company's financial parameters, such as fixed-charge coverage, at a minimum level. Because of the overriding relationship between a parent and a captive finance subsidiary, the financial strength of the parent is an important variable in the analysis of the finance company. However, captive finance companies can have ratings either above or below those of the parent.

A wholly owned finance company differs from a captive in two ways. First, it primarily finances the goods and services of companies other than the parent. Second, maintenance agreements between the parent and the subsidiary generally are not as formal. Frequently, there are indenture provisions that address the degree to which a parent can upstream dividends from a finance subsidiary. The purpose of these provisions is to prevent a relatively weak parent from draining a healthy finance subsidiary to the detriment of the subsidiary's bondholders.

Independent finance companies are either publicly owned or closely held. Because these entities have no parent, the analysis of this finance sector is strictly a function of the strengths of the company.

Financial Analysis

In analyzing finance companies, several groups of ratios and other variables should be considered. There is more of an interrelationship between these ratios and variables than for any other type of company. For example, a finance company with a high degree of leverage and low liquidity may be considered to be of high investment quality if it has a strong parent and maintenance agreements. Variables should be viewed not in isolation but rather within the context of the whole finance company–parent company relationship.

Asset Quality

The most important variable in analyzing a finance company is asset quality. Unfortunately, there is no definitive way to measure asset quality. However, there are several variables that in the aggregate present a good indication of asset quality.

Diversification is one measure of portfolio quality. Is the portfolio diversified across different types of loans? If the company is concentrated in or deals exclusively in one lending type, is there geographic diversification? A company that deals exclusively in consumer loans in the economically sensitive Detroit area would not be viewed as favorably as a company with broad geographic diversification. Accounting quality is also an important factor in

assessing portfolio quality. The security for the loans is also an important variable in portfolio quality. The stronger the underlying security, the higher is the loan quality. Analysts should be concerned primarily with the level of loans compared with levels of similar companies and the risk involved in the type of lending. For example, the expected loan loss from direct unsecured consumer loans is higher than for consumer loans secured by second mortgages. However, the higher fees charged for the former type of loan should compensate the company for the higher risk.

Numerous ratios of asset quality such as loss reserves/net charge-offs, net losses/average receivables, and nonperforming loans/average receivables give good indications of asset quality. However, finance companies have a high level of discretion in terms of what they consider and report to be nonperforming loans and what loans they charge off. Therefore, unadjusted ratios are not comparable among companies. In addition, companies periodically change their charge-off policies.

Despite the drawbacks of the asset-quality ratios, they are useful in indicating trends in quality and profitability. Of these ratios, loss reserves/net charge-offs is perhaps the most important ratio in that it indicates how much cushion a company has. A declining ratio indicates that the company may not be adding sufficient reserves to cover future charge-offs. Such a trend may lead to a future significant increase in the reserves and therefore a decrease in earnings as the increase is expensed. Net losses/average receivables and nonperforming loans/average receivables are other indicators of asset quality. An increasing ratio indicates a deterioration in quality. Declines may be exacerbated by an overall contraction or slow growth in the receivables. On the other hand, because of different accounting treatments, a stable net losses/average receivables ratio under deteriorating economic conditions may indicate a delay in loss recognition. Consideration also should be given to the age of receivables. In recent years, some finance companies have increased their lending dramatically over a short period of time and reported material improvement in their overall financial parameters. These results have been misleading in some cases where the dramatic improvement has been driven by inadequate reserves. Often the dramatic improvement has been followed by increased losses as the portfolio ages.

The long-term history of a company is also an indicator of credit quality. Does management have a history of managing risk conservatively? How long has management been in place? Is there pressure on management to accelerate growth? Has management responded to this type of pressure by expanding into more risky businesses either through acquisition or internal expansion?

Leverage

Leverage is a second important ratio used in finance company analysis. By the nature of the business, finance companies typically and acceptably are more highly leveraged than industrial companies. The leverage is necessary to earn a sufficient return on capital. However, the acceptable range of leverage depends on

other factors, such as parental support, portfolio quality, and type of business. The principal ratio to determine leverage is total debt to equity, although such variations as total liabilities to equity also may be used. In a diversified company with high portfolio quality, a leverage ratio of 5 to 1 is acceptable. On the other hand, a ratio as high as 7 to 1 is acceptable for a captive with a strong parent and maintenance agreements. The analyst always should view the leverage of a finance company in comparison with similar companies.

Liquidity

The third important variable in finance company analysis is liquidity. Because of the capital structure of finance companies, the primary cause of bankruptcies in this industry is illiquidity. If for some reason a finance company is unable to raise funds in the public or private market, failure can follow quickly. This inability to raise funds could result from internal factors, such as a deterioration in earnings, or from external factors, such as a major disruption in the credit markets. Whatever the cause, a company should have some liquidity cushion. The ultimate fallback, a sale of assets, is only a last resort because the sales could have long-term detrimental effects on earnings. The traditional liquidity ratio is cash, cash equivalents, and receivables due within one year divided by short-term liabilities. The higher this ratio, the higher is the margin of safety. Also to be considered are the liquidity of the receivables themselves and the existence of bank lines of credit to provide a company with short-term liquidity during a financial crisis. Liquidity calculations also should consider contractual obligations to fund loans. In general, the smaller and weaker companies should have a higher liquidity cushion than companies with strong parental backing that can rely on interest-free loans from their parents in times of market stress. Finally, analysts should take into account a company's ability to raise secured funding, either from banks or private investors or through asset-backed securities facilities.

Asset Coverage

A fourth important variable in the analysis of finance companies that is related to the three variables just discussed is the asset coverage afforded the bondholder. In assessing asset protection, the analyst should consider the liquidation value of the loan portfolio.

A definitive assessment of the value of assets is difficult because of the flexibility finance companies have in valuing assets. For example, a finance company that plans to liquidate its commercial real estate portfolio over 12 months in a depressed real estate environment will value its assets much lower than if it planned to sell the same assets systematically over a three- to five-year period. The value of interest-only securities (IOs) created from a finance company's asset securitizations is also subjective and depends on future credit experience and prepayments. Is management conservative or aggressive in valuing these instruments? How has management valued the residuals of automobile leases? Are there periodic write-offs or gains on these loans?

Earnings Record

The fifth variable to be considered is the finance company's earnings record. The industry is fairly mature and is somewhat cyclical. The higher the annual EPS growth, the better. However, some cyclicality should be expected. In addition, the analyst should be aware of management's response to major changes in the business environment. The easing of personal bankruptcy rule over the years and the fact that personal bankruptcy is becoming more socially acceptable have produced significantly higher loan losses in direct, unsecured consumer loans. Many companies have responded to this change by contracting their unsecured personal loans and expanding their portfolios invested in personal loans secured by second mortgages.

Management

The sixth variable to be considered is the finance company's management. This variable is difficult to assess. However, a company visit combined with an evaluation of business strategies and credit scoring methodologies (analysis used for assessing loan applicants) will provide some insight into this variable.

Size

A final factor related to the finance company or subsidiary is size. In general, larger companies are viewed more positively than smaller companies. Size has important implications for market recognition in terms of selling securities and of diversification. A larger company can more easily diversify the types and geographical location of its loans, thereby lessening the risk of its portfolio, than a smaller company can.

In addition to an analysis of the financial strength of the company according to the preceding variables, the analyst must incorporate the net effect of any affiliation the finance company has with a parent. If this affiliation is strong, it may be the primary variable in the credit assessment. The affiliation between a parent company and a finance subsidiary is straightforward; it is captive, wholly owned, or independent. However, the degree to which a parent will support a finance subsidiary is not as straightforward. Traditionally, the integral relationship between a parent and a captive finance subsidiary has indicated the highest level of potential support. However, it is becoming increasingly clear that a wholly owned finance subsidiary can have just as strong an affiliation. For example, General Electric Capital finances few or no products manufactured by its parent, General Electric Company (GE). GE, however, receives substantial tax benefits from its consolidation of its tax return with GE Capital. Additionally, GE has a sizable investment in the finance subsidiary. In this case, the parent also has a formal agreement with GE Capital by which it is committed to infuse capital if fixed charge coverage of $1.1 \times$ is not maintained. Even aside from that mechanism, there is a strong presumption that GE would protect its investment in GE Capital if the finance subsidiary were to need assistance. In other cases, the benefit of a strong affiliation and maintenance agreement may be offset by weakness in the parent company's financial position.

In addition to affiliation, affiliate profitability, and maintenance agreements, the analyst also should examine any miscellaneous factors that could affect the credit standing of the finance company. For example, new legislation could produce significant changes in the finance industry's structure or profitability. Cases in point of recent years include the Bankruptcy Abuse Prevention and Consumer Protection Act of 2005 and the Dodd-Frank Wall Street Reform and Consumer Protection Act of 2010.

THE ANALYSIS OF HIGH-YIELD CORPORATE BONDS

High-yield bonds, sometimes disparagingly referred to as "junk bonds," are corporate issues rated speculative grade (below Baa/BBB–). Like all corporate bonds, they combine interest rate risk with credit risk, but unlike investment-grade issues, credit risk dominates their price movements. The high-yield universe is split between fallen angels, which are bonds rated investment-grade at issuance and subsequently downgraded to speculative grade, and original issue high-yield bonds that were rated speculative grade at issuance. Fallen angels have the disadvantage of the looser covenants associated with their original ratings. In many cases, however, they are run by managers who are strongly motivated to recapture their investment-grade ratings through prudent financial policies that can lead to upgrading. Original issue high-yield bonds offer the advantage of stronger covenants and in some cases, the possibility that as comparatively new issuers that are not yet widely known, they are underrated by the rating agencies and undervalued by bond investors.

Many of the tools employed in evaluating investment-grade bonds can also be applied to high-yield issues, but the emphasis of the analysis is different. In contrast to the investment-grade universe, where it is extremely rare for a company to go directly to default, an average of more than 4% of speculative grade issuers default each year.[5] As a consequence, high-yield analysts must focus intensely on the downside in a company's operations, its sources of liquidity, and the salvage value of its assets in the event of default.

The price of a company's high-yield bonds, like its stock price, can be highly sensitive to minor changes in the earnings outlook. High-yield analysts therefore operate much as equity analysts do in participating in companies' earnings calls and tracking industry data that may shed light on future profits. They go beyond their equity counterparts in studying the details of the issuers' funding capability and covenant provisions, which become highly pertinent under conditions of financial stress.

The following sections address aspects of credit analysis that require expanded attention in the analysis of high-yield corporate bonds.

5. Source: Moody's Investors Service.

Competition

In the popular mind, high-yield companies are small players in their markets, yet over the years there have been many exceptions to this stereotype. Examples include the three largest U.S. automakers (General Motors, Ford Motor Company, and Chrysler), the world's largest operator of health care facilities (HCA), and the world's largest casino operator (Caesars Entertainment). Size does not automatically confer a competitive advantage, nor do smaller companies invariably report inferior profit margins due to a lack of scale economies. Instead of participating in all market segments, including mature and highly competitive ones, some small companies manage to carve out highly profitable niches. They do not strive to minimize unit costs by maximizing volume, but instead obtain premium prices by offering superior selection or convenience.

By the same token, analysts should not accept at face value the glib assertions of high-yield market promoters that the rating agencies arbitrarily and mistakenly penalize companies for being small. The agencies do not rate companies speculative grade because they are small, but rather because of certain consequences of their smallness.

Some small companies lack geographical diversification and are therefore highly vulnerable to a regional economic downturn. Others have no credible succession plans in place because domination by strong-willed founders makes it difficult for them to attract and retain capable candidates at the next level of management. Neither should analysts assume, as private equity firms probably would like them to, that a high level of equity ownership by key employees is so powerful a motivator that corporate failure is inconceivable.

Cash Flow

One of the most important elements in analyzing a high-yield security is cash flow. In recent years, analysts have concentrated increasingly on *free cash flow* (FCF), defined as cash flow from operations minus capital expenditures. FCF can be calculated as follows:

EBIT × (1 – Tax Rate)
+ Depreciation and Amortization
– Changes in Working Capital
– Capital Expenditures
= Free Cash Flow

A company that generates free cash flow is not dependent on external financing and therefore should not be stymied by a temporary unavailability of credit. In addition, FCF generators are best positioned to refinance maturing debt during periods when capital markets are open, but only to the strongest high-yield

borrowers. For a company in this select group, investors theoretically need concern themselves only with the risk that positive FCF generation will prove unsustainable.

The rise in popularity of free cash flow is partly a reaction to abuse of a popular cash-flow proxy of earlier decades, EBITDA. In the 1990s, competition for deals pushed the debt loads on leveraged buyouts (LBOs) to an extreme that made issuers look very weak by standard financial ratios such as EBITDA/Interest Expense. Underwriters responded by promoting "adjusted EBITDA." The newfangled ratio conveniently eliminated the impact of operating losses that were deemed to reflect "restructurings," which was too often a euphemism for failed investments. Even before this distortion of reality became common, EBITDA had serious shortcomings as a cash-flow measure by virtue of ignoring capital expenditures and working capital requirements. These are essential cash uses that a company may have difficulty funding in a period of tight credit.

For all its faults, EBITDA remains the high-yield market's standard for calculating leverage. Analysts view a company's total debt outstanding as some number of "turns" of EBITDA. Suppose, for instance, that a company's debt is equivalent to four × its EBITDA at a time when corporate buyers and LBO sponsors are paying six × EBITDA to acquire comparable companies. Bondholders will feel comfortable that in the event of default they will fully recover their principal from the proceeds of a sale of the company in bankruptcy. As with free cash flow, the key assumption is that the level of cash generation will not fall. Proceeds equivalent to six × a greatly reduced EBITDA will not be as great as the company's debt load.

Net Assets

In analyzing a bond, the analyst must ascertain or at least approximate the liquidation value of the assets. Are these assets valued properly on the balance sheet? Of particular interest may be real estate holdings. For example, in analyzing the gaming companies, a market assessment of land holdings should be included. On the other hand, one also should consider the likelihood of those assets being available for liquidation, if necessary. To whom do they belong? Are they mortgaged or being used as collateral? Assets are occasionally spun off to the equity owners of the company. In such a circumstance, the bondholders may experience a sudden and dramatic deterioration of credit quality. Other bondholders are secured by specific assets such as railroad cars or a nuclear power station. In these circumstances, the value and marketability of the collateral must be ascertained. Collateral, by definition, must be specific, and so must be the analysis. Ten railroad engines may appear to provide adequate collateral until it is discovered that the engines are not only obsolete but have not been maintained for a number of years. Five aircraft may appear to be adequate collateral until it is discovered that the engines were financed separately and do not constitute collateral.

Particular attention must be paid to the asset protection in a takeover situation. In this instance, assets that originally provided protection for an investor's holdings could be used to secure new debt senior to the investor's position.

The analyst also must focus on the location of the assets. If the assets are in a foreign country, the analyst should be familiar with that country's laws regarding expatriation of funds. In the extreme case, the analyst should be familiar with that country's laws regarding bankruptcy proceedings. Notwithstanding high-yield investors' traditional claim that they focus on the verifiable values of hard assets, it is in fact common to attribute substantial value to certain items that do not even qualify as assets under generally accepted accounting principles. For example, media and telecommunications companies are often evaluated by attributing a dollar amount to each customer or potential customer. Current valuations may be justified by the prices being paid for comparable properties in mergers and acquisitions transactions. In the future, however, the value of these unofficial assets may evaporate as new technologies emerge to provide communications services more cheaply or more effectively. There is also a risk that if a company becomes financially distressed its existing customers (particularly business customers) may switch to other providers.

Management

Management is a critical element in the assessment of any company. Given enough time, poor management can bankrupt the most prosperous enterprise. Conversely, good management is essential to the long-run survival of all firms.

Many successful firms are launched by the top engineers or salespeople at industry-leading firms. They may bring strong talent and motivation, but analysts must evaluate the entire team to ensure that all key functions are in capable hands. Does the company have a strong financial manager? Are proper controls in place? Incentives can also play a significant role in determining a company's long-run success. Ownership of a significant portion of the company by management is generally a positive, if not necessarily a panacea.

There are two principal ways to evaluate management. The first is to judge the team by its results. This is accomplished through financial analysis. The second way is to meet with senior managers to judge first-hand their vision for the firm as well as their understanding of the business. This is achieved by attending new-financing road shows, as well as arranging one-on-one meetings where possible, and participating in companies' quarterly earnings calls.

An analyst must be well-prepared for meetings with management. Lack of preparation creates the risk of being swayed by a slick presentation that lacks true substance. In one presentation to potential bond investors, the senior management of a company that manufactured gas pump nozzles stated that European operations would generate major growth because of increased environmental requirements to reduce gasoline fumes at service stations. In an effort to estimate the potential for this new revenue opportunity, an analyst asked management to

discuss the state of European environmental laws and how they differed from laws in the United States. Management was unable to answer the question. The company subsequently filed for bankruptcy.

Leverage

Companies that issue high-yield bonds generally are highly leveraged. Leverage per se is not harmful and in many circumstances is beneficial to growth. However, the degree of leverage should be evaluated in terms of its effect on the financial flexibility of the firm. As pointed out earlier, leverage should be calculated on absolute and market-adjusted bases. The most common approach to market adjustment is to calculate a market value for the equity of the firm. To the extent that the common stock is selling below book value, leverage will be understated by a traditional approach. Some firms also adjust the market value of debt in calculating leverage. This approach is interesting, but a consistent approach must be employed when convertibles are considered in the equity equation. The benefit of adjusting the equity side of the leverage equation is clear. As the market values a company's equity upward, the market is indicating a willingness to support more leverage. A similar increase in the market adjustment of a firm's debt may indicate an upward appraisal of creditworthiness or an overall lowering of interest rates. In either case, the company probably would have the opportunity to refinance at a lower cost and thereby increase profitability.

Care also should be taken to evaluate sources of leverage that are not stated clearly on the balance sheet. These sources arise from the use of complicated financings.[6] For example, consider deferred-coupon bonds that are commonly used by high-yield issuers. Deferred-coupon bonds permit the issuer to postpone interest payment to some future year. As a result, the interest burden is placed on future cash flow to meet the interest obligations. Because of this burden, the presence of deferred-coupon bonds may impair the ability of the issuer to improve its credit quality in future periods. Moreover, if senior bonds have deferred-coupon payments, the subordinated bonds will be adversely affected as the amount of senior bonds increases over time relative to the amount of subordinated bonds. For example, one type of deferred-coupon bond that has been widely used in some years is the payment-in-kind (PIK) bond. With this bond structure, a high-yield issuer has the option either to pay interest in cash or pay the equivalent of interest with another bond with the same coupon rate. If the issuer does not have the ability to pay the interest in cash, payment with another bond will increase future interest expense and thereby adversely affect the issuer's future cash flow. If the PIK bonds are senior bonds, subordinated bonds are adversely affected over time as more senior bonds are added to the capital structure and future interest expense is increased further.

6. William A. Cornish, "Unique Factors in the Credit Analysis of High-Yield Bonds," in Frank K. Reilly (ed.), *High-Yield Bonds: Analysis and Risk Assessment* (Charlottesville, VA: Association for Investment Management and Research, 1990).

Corporate Structure

High-yield issuers usually have a holding-company structure. The assets to pay creditors of the holding company will come from the operating subsidiaries. It is therefore, critical to analyze the corporate structure. Specifically, the analyst must understand how cash will be passed between subsidiaries and the parent company and among the subsidiaries. The corporate structure may be so complex that the payment structure becomes confusing.

For example, in the mid 2000s Charter Communications created a dizzyingly complex corporate structure. The cable television systems operator capitalized on its rapidly growing EBITDA to create and further leverage a succession of new intermediate holding companies. Eventually, the operating subsidiaries stood beneath a parent operating company and eight layers of holding companies with names such as Charter Communications Holding Company, LLC, Charter Communications Holdings, LLC, and CCH I Holdings, LLC.

Simply calculating financial ratios for the consolidated company did not produce an accurate picture of Charter's debt-servicing capability. Each holding company's ability to make interest payments depended on dividends from the companies positioned below it on the corporate totem pole. Those companies could not lawfully pay dividends before meeting their own debt service requirements and they were further constrained by restrictions, tied to leverage covenants, on upstreaming of dividends. This was an especially acute concern for holders of a convertible bond of the ultimate holding company, Charter Communications, Inc. (CCI).

Charter kept its highly leveraged web of companies solvent by frequently tapping the capital markets to retire maturing debt. Extensive intercompany loans further complicated the picture. The game ended when a financial crisis shut the markets down. Charter filed for bankruptcy in 2009 and the importance of mastering the intricacies of high-yield analysis once again became apparent. Senior secured lenders at the parent operating company and at the holding companies just above it, who were closest to the assets, recovered 100% of their principal. In contrast, note holders at some of the more remote holding companies recovered negligible amounts. Somewhat anomalously, convertible bond holders at CCI, who were furthest of all from the assets, enjoyed a higher percentage recovery than creditors of some intermediate holding companies. This was achieved partly with cash proceeds of the sale of the convertible issue, which had been retained at CCI to cover interest payments.

Covenants

While an analyst should consider covenants when evaluating any bond issue (investment-grade or high-yield), it is particularly important for the analysis of high-yield issuers. The importance of understanding covenants was summarized by one high-yield portfolio manager as follows:

> Covenants provide insight into a company's strategy. As part of the credit process, one must read covenants within the context of the corporate strategy. It is not sufficient to hire a lawyer to review the covenants because a lawyer might miss the critical factors necessary to make the appropriate decision. Also, loopholes in covenants often provide clues about the intentions of management teams.[7]

Note, however, that some specialized consulting firms offer assistance in interpreting covenants, combining financial sophistication with legal expertise.

Definitions

Great care must be paid to definitions. As discussed earlier with respect to cash flow, definitions can materially skew cash-flow projections. When asked to define certain terms, management often will state that its definitions are "standard." There is no standard definition.

Definitions also should be evaluated in covenants. For example, a "change of control" typically triggers a 101% put option for the bondholder, but the term does not necessarily refer to all changes in controlling interest in the company. A change of control may be defined to include an acquisition of the company but not a merger (in which the company's separate corporate structure disappears). In some cases, acquisition by a major existing shareholder is excluded from the definition.

CREDIT SCORING MODELS

To this point in the chapter, the focus has been on traditional ratios and other measures that credit analysts use in assessing default risk. Several researchers have used these measures as input to assess the default risk of issuers using the statistical technique of multiple discriminant analysis (MDA). This tool is primarily a classification technique that is helpful in distinguishing between or among groups of objects and in identifying the characteristics of objects responsible for their inclusion in one or another group. One of the chief advantages of MDA is that it permits a simultaneous consideration of a large number of characteristics and does not restrict the investigator to a sequential evaluation of each individual attribute. For example, MDA permits a credit analyst studying ratings of corporate bonds to examine, at one time, the total and joint impact on ratings of multiple financial ratios, financial measures, and qualitative factors. The analyst is thereby freed from the cumbersome and possibly misleading task of looking at each characteristic in isolation from the others. MDA seeks to form groups that are internally as similar as possible but that are as different from one another as possible.

---

7. Robert Levine, "Unique Factors in Managing High-Yield Bond Portfolios," in *High-Yield Bonds: Analysis and Risk Assessment*. p. 35.

From the preceding description of MDA it can be seen why it has been applied to problems of why bonds get the ratings they do and what variables seem best able to account for a bond's rating. Moreover, MDA has been used as a predictor of bankruptcy. While the steps involved in MDA for predicting bond ratings and corporate bankruptcies are a specialist topic, the following discussion addresses the results of the work of Edward Altman, the primary innovator of MDA for predicting corporate bankruptcy.[8] The models of Altman and others involved in this area are updated periodically. Here the purpose is only to provide an illustration of how MDA models work.

In one of Altman's earlier models, referred to as the "Z-score model," he found that the following MDA could be used to predict corporate bankruptcy.[9]

$$Z = 1.2X_1 + 1.4X_2 + 3.3X_3 + 0.6X_4 + 1.0X_5$$

where

X_1 = working capital/total assets (in decimal)
X_2 = retained earnings/total assets (in decimal)
X_3 = earnings before interest and taxes/total assets (in decimal)
X_4 = market value of equity/total liabilities (in decimal)
X_5 = sales/total assets (number of times)
Z = Z-score

Given the value of the five variables for a given firm, a Z-score is computed. The Z-score is used to classify firms with respect to whether or not there is potentially a serious credit problem that would lead to bankruptcy. Specifically, Altman found that Z-scores of less than 1.81 indicated a firm with serious credit problems, whereas a Z-score in excess of 3.0 indicated a healthy firm.

Subsequently, Altman and his colleagues revised the Z-score model based on more recent data. The resulting model, referred to as the "zeta model" found that the following seven variables were important in predicting corporate bankruptcies and were highly correlated with bond rating:[10]

- Earnings before interest and taxes (EBIT)/total assets
- Standard error of estimate of EBIT/total assets (normalized) for 10 years
- EBIT/interest charges
- Retained earnings/total assets

10. Edward I. Altman, Robert G. Haldeman, and Paul Narayann, "Zeta Analysis: A New Model to Identify Bankruptcy Risk of Corporations," *Journal of Banking and Finance* (June 1977), pp. 29–54.

- Current assets/current liabilities
- Five-year average market value of equity/total capitalization
- Total tangible assets, normalized

While credit scoring models have been found to be helpful to analysts and bond portfolio managers, they do have limitations as a replacement for human judgment in credit analysis. Quantitative models are effective in identifying companies that share certain characteristics with defaulting companies, but many of the companies identified by the models do not default. One thing a statistical model cannot readily spot is the possibility of bringing in new management that will turn the company around and prevent a default. Therefore, an investor who is faced with a potentially large loss on a distressed company may benefit from assessing a company's prospects for redirecting itself, rather than selling based solely on a quantitative score. In practice, professional high-yield bond and distressed-debt managers do not rely entirely on models such as the Z-score, but at most use them to supplement their own hands-on analysis.

KEY POINTS

- Credit analysis has evolved from exclusive focus on default risk in a buy-and-hold strategy to playing a role in active management of corporate bond portfolios.
- Equity-related information can help to create a systematic analysis, but it is important also to consider other determinants of credit risk.
- Key areas of a credit assessment include industry analysis, financial analysis, and indenture provisions.
- Analysis of high-yield, or speculative-grade, corporate bonds requires particular focus on the downside in a company's operations, its cash flow, and the quality of its management.
- Quantitative credit scoring models cannot replace hands-on credit analysis, but can usefully supplement it.

CHAPTER
FORTY-FOUR

THE CREDIT ANALYSIS OF MUNICIPAL GENERAL OBLIGATION AND REVENUE BONDS

SYLVAN G. FELDSTEIN, PH.D.
Director
Investment Department
Guardian Life Insurance Company of America

ALEXANDER GRANT
Portfolio Manager, RS Tax-Exempt and
RS High Yield Municipal Bond Funds

DAVID RATNER, CFA
Industry Consultant

The degree of safety of investing in municipal bonds has been considered second only to that of U.S. Treasury bonds, but beginning in the fourth quarter of the last century, ongoing concerns developed among many investors and underwriters about the potential default risks of municipal bonds.

One concern resulted from the well-publicized billion-dollar general obligation note defaults in 1975 of New York City. Not only did specific investors face the loss of their principal, but the defaults sent a loud and clear warning to municipal bond investors in general. The warning was that regardless of the supposedly ironclad legal protections for the bondholder, when issuers have severe budget-balancing difficulties, the political hues, cries, and financial interests of public employee unions, vendors, and community groups may be dominant forces in the initial decision-making process.

This reality was further reinforced by the new federal bankruptcy law that took effect on October 1, 1979, which makes it easier for municipal bond issuers to seek protection from bondholders by filing for bankruptcy. One by-product of the increased investor concern is that since 1975, the official statement, which is the counterpart to a prospectus in an equity or corporate bond offering and is to contain a summary of the key legal and financial security features, has become more comprehensive. As an example, before 1975 it was common for a city of New York

official statement for a general obligation bond sale to be only six pages long, whereas for a bond sale at the end of 2003 it was 165 pages long.

More recently, with the recession that began in December of 2007 and the well-publicized bond defaults of both Vallejo, California (in Chapter 9 under the U.S. Bankruptcy Code), and Harrisburg, Pennsylvania (considering a Chapter 9 filing) as well as the budgetary stresses of many large states and cities, the credit quality of municipal bonds has received increased attention.

The second reason for the increased interest in credit analysis was derived from the changing nature of the municipal bond market. It is now characterized by strong buying patterns by private investors and institutions. The patterns were caused in part by high federal, state, and local income tax rates. Tax-exempt bonds increasingly have become an important and convenient way to shelter income. One corollary of the strong buyers' demand for tax exemption has been an erosion of the traditional security provisions and bondholder safeguards that had grown out of the default experiences of the 1930s. General obligation bond issuers with high tax and debt burdens, declining local economies, and chronic budget-balancing problems had little difficulty finding willing buyers. Also, revenue bonds increasingly were rushed to market with legally untested security provisions, modest rate covenants, reduced debt reserves, and weak additional-bond tests. Because of this widespread weakening of security provisions, it has become more important than ever before that the prudent investor carefully evaluate the creditworthiness of a municipal bond before making a purchase.

This concern has been increased when the rating agencies in 2009 recalibrated their ratings upward on many general obligation and essential service revenue bonds. They argued that municipal bond issues probably should have slightly better ratings relative to corporate bonds in the context of both historical default rates and recovery levels following default. This resulted in higher ratings on many municipal bonds.

In analyzing the creditworthiness of a general obligation, tax-backed, or pure revenue bond, the investor should cover five categories of inquiry: (1) legal documents and opinions, (2) politics/management, (3) underwriter/financial advisor, (4) general credit indicators and economics, and (5) red flags, or danger signals.

The purpose of this chapter is to set forth the general guidelines that the investor should rely upon in asking questions about specific bonds.

THE LEGAL OPINION

Popular opinion holds that much of the legal work done in a bond issue is boilerplate in nature, but from the bondholder's point of view the legal opinions and document reviews should be the ultimate security provisions because, if all else fails, the bondholder may have to go to court to enforce his or her security rights. Therefore, the integrity and competency of the lawyers who review the documents and write the legal opinions that usually are summarized in the official statements are very important.

The relationship of the legal opinion to the analysis of municipal bonds for both general obligation and revenue bonds is threefold. First, the lawyer should check to determine whether the issuer is indeed legally able to issue the bonds. Second, the lawyer is to see that the issuer has properly prepared for the bond sale by enacting the various required ordinances, resolutions, and trust indentures and without violating any other laws and regulations. This preparation is particularly important in the highly technical areas of determining whether the bond issue is qualified for tax exemption under federal law and whether the issue has been structured in such a way as to not violate federal arbitrage regulations. Third, the lawyer is to certify that the security safeguards and remedies provided for the bondholders and pledged by either the bond issuer or third parties (such as banks with letter-of-credit agreements) are actually supported by federal, state, and local government laws and regulations.

General Obligation Bonds

General obligation bonds are debt instruments issued by states, counties, towns, cities, and school districts. They are secured by the issuers' general taxing powers. The investor should review the legal documents and opinion as summarized in the official statement to determine what specific *unlimited* taxing powers, such as those on real estate and personal property, corporate and individual income taxes, and sales taxes, are legally available to the issuer, if necessary, to pay the bondholders. Usually for smaller governmental jurisdictions, such as school districts and towns, the only available unlimited taxing power is on property. If there are statutory or constitutional taxing power limitations, the legal documents and opinion should clearly describe how they affect the security of the bonds.

For larger general obligation bond issuers, such as states and big cities that have diverse revenue and tax sources, the legal opinion should indicate the claim of the general obligation bondholder on the issuer's general fund. Does the bondholder have a legal claim, if necessary, to the first revenues coming into the general fund? This is the case with bondholders of state of New York general obligation bonds. Does the bondholder stand second in line? This is the case with bondholders of state of California general obligation bonds. Or are the laws silent on the question altogether? This is the case for most other state and local governments.

Additionally, certain general obligation bonds, such as those for water and sewer purposes, are secured in the first instance by user charges and then by the general obligation pledge. (Such bonds are popularly known as being "double barreled.") If so, the legal documents and opinion should state how the bonds are secured by revenues and funds outside the issuer's general taxing powers and general fund.

Revenue Bonds

Revenue bonds are issued for project or enterprise financings that are secured by the revenues generated by the completed projects themselves, or for general

public-purpose financings in which the issuers pledge to the bondholders tax and revenue resources that were previously part of the general fund. This latter type of revenue bond, sometimes known as a "dedicated tax bond," is usually created to allow issuers to raise debt outside general obligation debt limits and without voter approvals. The trust indenture and legal opinion for both types of revenue bonds should provide the investor with legal comfort in six bond-security areas:

- The limits of the basic security
- The flow-of-funds structure
- The rate, user-charge, or dedicated revenue and tax covenants
- The priority of pledged revenue claims
- The additional-bonds test
- Other relevant covenants and issues

The Limits of the Basic Security

The legal documents should explain what the pledged revenues for the bonds are and how they may be limited by federal, state, and local laws. The importance of this is that although most revenue bonds are structured and appear to be supported by identifiable revenue streams, those revenues sometimes can be negatively affected directly by other levels of government. For example, the state of Wyoming in the early 1980s issued Mineral Royalties Revenue Bonds. On the surface, the bond issue had all the attributes of a revenue bond. The bonds had a first lien on the pledged revenues, and additional bonds could only be issued if a coverage test of 125% was met. Yet the revenues to pay bondholders were to be received by the state from the federal government as royalty payments for mineral production on federal lands. The U.S. Congress was under no legal obligation to continue this aid program. Therefore, the investor must read carefully the legal documents to learn if there are shortcomings of the bond security.

More recently, in 2011 the governor of California proposed eliminating local redevelopment agencies and transferring their tax increment revenues to other purposes. In a worst-case scenario if all the revenues were taken away, there would be no monies left to pay the redevelopment agency bondholders. The governor did not propose this, but the legal documents should indicate that this could happen.

The Flow-of-Funds Structure

The legal documents should explain what the bond issuer has promised to do concerning the pledged revenues received. What is the order of the revenue flows through the various accounting funds of the issuer to pay for the operating expenses of the facility, payments to the bondholders, maintenance and special capital improvements, and debt service reserves? This sometimes is referred to as

the "waterfall." Additionally, the legal documents should indicate what happens to excess revenues after they pass through the waterfall. Do they go to the issuer's general fund or do they stay within the indenture to be used to call bonds or make capital repairs.

The flow of funds of many revenue bonds is structured as *net revenues* (i.e., debt service is paid to the bondholders immediately after revenues are paid to the basic operating and maintenance funds, but before paying all other expenses). A *gross revenues* flow-of-funds structure is one in which the bondholders are paid even before the operating expenses of the facility are paid. Examples of gross revenue bonds are those issued by the New York Metropolitan Transportation Authority. However, although it is true that these bonds legally have a claim to the fare-box revenues before all other claimants, it is doubtful that the system could function if the operational expenses, such as wages and electricity bills, were not paid first.

The Rate, User-Charge, or Dedicated Revenue and Tax Covenants

The legal documents should indicate what the issuer has legally committed itself to do to safeguard the bondholders. If user rates are involved do they only have to be sufficient to meet expenses, including debt service, known as one times debt service coverage. Is the one-time coverage test calculated for the *average annual debt* service requirement or for the higher *maximum annual debt service* one? Additionally, is the coverage requirement for higher amounts such as 1.1 times or 1.25 times so as to provide for reserves? The legal documents should indicate whether or not the issuer has the legal power to increase rates or charges of users without having to obtain prior approvals by other governmental units.

The Priority of Pledged Revenue Claims

The legal documents should state whether or not other levels of government or claimants can legally tap the revenues of the issuer even before they start passing through the issuer's flow-of-funds structure. An example would be the highway revenue bonds issued by the Puerto Rico Highway Authority. These bonds are secured in part by the revenues from the Commonwealth of Puerto Rico gasoline tax. Yet, if in a worst case scenario no other funds are available to pay their debt service, under the Commonwealth's constitution the moneys are first to be applied to the Commonwealth's own general obligation bonds.

The Additional-Bonds Test

The legal documents should indicate under what circumstances the issuer can issue additional bonds that share equal claims to the issuer's revenues. Usually, the legal requirement is that the maximum annual debt service on the new bonds as well as on the old bonds be covered by the projected net revenues by a specified minimum amount. This can be as low as one times coverage. Some revenue bonds have stronger additional-bonds tests to protect the bondholders. Also, how the historical revenues are calculated is important. Can the issuer select specific

prior months to be used such as 12 out of the last 15 months? Who determines the projection numbers for the future revenues? Is it an independent consultant with expertise in the area? How conservative are the projections and how are they certified? Additionally, the definition of revenues is important. Does it include revenues generated by the enterprise, or could it also include special supplemental payments? These are all questions that have to be addressed by the analyst in reviewing the additional bonds test formula.

Other Relevant Covenants and Issues

Lastly, the legal documents should indicate whether there are other relevant covenants for the bondholder's protection. These usually include pledges by the issuer of the bonds to insure the project (if it is a project-financing revenue bond), to have the accounting records of the issuer annually audited by an outside certified public accountant and provide timely reports to investors, and to employ independent engineers to annually review the capital plant and make mandatory recommendations to keep the facility operating for the life of the bonds.

In addition to the above aspects of the specific revenue structures of general obligation and revenue bonds, two other developments over the recent past make it more important than ever for the investor to carefully review the legal documents and opinions summarized in the official statements. The first development involves the mushrooming of new financing techniques that may rest on legally untested security structures. The second development is the increased use of legal opinions provided by local attorneys who may have little prior municipal bond experience. (Legal opinions traditionally have been written by experienced municipal bond attorneys.)

Legally Untested Security Structures and New Financing Techniques

In addition to the more traditional general obligation bonds and toll road, bridge, and tunnel revenue bonds, there are now more non-voter-approved, innovative, and legally untested security mechanisms. These innovative financing mechanisms include lease-rental bonds, moral obligation housing bonds, "dedicated tax-backed" and structured "asset-backed" bonds, take-and-pay power bonds with step-up provisions requiring the participants to increase payments to make up for those that may default, commercial bank-backed letter-of-credit "put" bonds, and tax-exempt commercial paper. What distinguishes these newer bonds from the more traditional general obligation and revenue bonds is that they have little history of court decisions and other case law to firmly protect the rights of the bondholders. For the newer financing mechanisms, the legal opinion should include an assessment of the probable outcome if the bond security were challenged in court. Note, however, that most official statements do not provide this to the investor.

The Need for Reliable Legal Opinions

For many years, concern over the reliability of the legal opinion was not as important as it is now. As a result of the numerous bond defaults and related shoddy legal opinions in the nineteenth century, the investment community demanded that legal documents and opinions be written by recognized municipal bond attorneys. As a consequence, over the years, a small group of primarily Wall Street-based law firms and certain recognized firms in other financial centers dominated the industry and developed high standards of professionalism.

Now, however, more and more issuers have their legal work done by local law firms, a few of whom have little experience in municipal bond work. This development, along with the introduction of more innovative and legally untested financing mechanisms, has created a greater need for reliable legal opinions. An example of a specific concern involves the documents the issuers' lawyers must complete so as to avoid arbitrage problems with the Internal Revenue Service.

By 2011, there were thousands of attorneys located throughout the country who were listed in the *Bond Buyers'* Municipal Marketplace directory. They presented themselves as being experts in municipal finance law and provided various security structure and tax opinions. Sorting out quality distinctions in their work and who is well grounded in the law, and who is not, is challenging.

On negotiated bond issues, one remedy has been for the underwriters to have their own counsels review the documents and to provide separate legal opinions.

THE NEED TO KNOW WHO REALLY IS THE ISSUER

Still another general question to ask before purchasing a municipal bond is just what kind of people are the issuers? Are they conscientious public servants with clearly defined public goals? Do they have histories of successful management of public institutions? Have they demonstrated commitments to professional and fiscally stringent operations? Additionally, issuers in highly charged and partisan environments in which conflicts chronically occur between political parties or among political factions or personalities are clearly bond issuers to scrutinize closely and possibly to avoid. Such issuers should be scrutinized regardless of the strength of the surrounding economic environment.

For General Obligation and Tax-Backed Bonds

For general obligation bond issuers, focus on the political relationships that exist among chief executives such as mayors, county executives, and governors, and among their legislative counterparts. Issuers with unstable political elites are of particular concern. Of course, rivalry among politicians is not necessarily bad. What is undesirable is competition so bitter and personal that real cooperation among the warring public officials in addressing future budgetary problems may

be precluded. An example of an issuer that was avoided because of such dissension *was* the city of Cleveland. The political problems of the city in 1978 and the bitter conflicts between Mayor Kucinich and the city council resulted in a general obligation note default in December of that year.

For Revenue Bonds

When investigating revenue bond issuers, it is important to determine not only the degree of political conflict, if any, that exists among the members of the bond-issuing body but also the relationships and conflicts among those who make the appointments to the body. Additionally, the investor should determine whether the issuer of the revenue bond has to seek prior approval from another governmental jurisdiction before the user fees or other charges can be levied. If this is the case, then the stability of the political relationships between the two units of government must be determined.

An important example involves the creditworthiness of the water and electric revenue bonds and notes issued by Kansas City, Kansas. Although the revenue bonds and notes were issued by city hall, it was the six-member board of public utilities, a separately elected body, that had the power to set the water and electricity rates. In the spring of 1981, because of a political struggle between a faction on the board of public utilities and the city commissioners (including the city's finance commissioner), the board refused to raise utility rates as required by the covenant. The situation came under control only when a new election changed the makeup of the board in favor of those supported by city hall.

In addition to the preceding institutional and political concerns, for revenue bond issuers in particular, the technical and managerial abilities of the staff should be assessed. The professional competency of the staff is a more critical factor in revenue bond analysis than it is in the analysis of general obligation bonds. The reason is that unlike general obligation bonds, which are secured in the final instance by the full faith and credit and unlimited taxing powers of the issuers, many revenue bonds are secured by the ability of the revenue projects to be operational and financially self-supporting.

The professional staffs of authorities that issue revenue bonds for the construction of nuclear and other public power-generating facilities, apartment complexes, hospitals, water and sewer systems, and other large public works projects, such as convention centers and sports arenas, should be reviewed carefully. Issuers who have histories of high management turnovers, project cost overruns, or little experience should be avoided by the conservative investor or at least considered higher risks than their assigned commercial credit ratings may indicate. Additionally, it is helpful for revenue bond issuers to have their accounting records annually audited by outside certified public accountants so as to provide the investor with a more accurate picture of the issuer's financial health.

ON THE FINANCIAL ADVISOR AND UNDERWRITER

Shorthand indications of the quality of the investment are (1) who the issuer selected as its financial advisor, if any; (2) its principal underwriter if the bond sale was negotiated; and (3) its financial advisor if the bond issue came to market competitively. Additionally, many prudent underwriters will not participate if there are significant credit-quality concerns. Therefore, it is also useful to learn who was the underwriter for the bond sales as well.

Identifying the financial advisors and underwriters is important for two reasons.

The Need for Complete, Not Just Adequate, Investment Risk Disclosures

The first reason relates to the quality and thoroughness of information provided to the investor by the issuer. The official statement, or private-placement papers if the issue is placed privately, is usually prepared with the assistance of lawyers and a financial advisor or by the principal underwriter. There are industry-wide disclosure guidelines that generally are adhered to, but not all official statements provide the investor with complete discussions of the risk potentials that may result from either the specific economics of the project or the community settings and the operational details of the security provisions. It is usually the author of this document who decides what to emphasize or downplay in the official statement. The more professional and established the author is in providing unbiased and complete information about the issuer, the more comfortable the investor can be with information provided by the issuer and in arriving at a credit-quality conclusion.

The Importance of Firm Reputation for Thoroughness and Integrity

By itself, the reputation of the issuer's financial advisor and/or underwriter should not be the determinant credit-quality factor, but it is a fact the investor should consider, particularly in the case of marginally feasible bond issues that have complex flow-of-funds and security structures. The securities industry is different from other industries, such as real estate, in that trading and investment commitments are usually made over the phone or electronically with a paper trail following days later. Many institutional investors, such as banks, bond funds, and property and casualty insurance companies, have learned to judge issuers by the company they keep. Institutions tend to be conservative, and they are more comfortable with financial information provided by established financial advisors and underwriters who have recognized reputations for honesty. Individual investors and analysts would do well to adopt this approach.

GENERAL CREDIT INDICATORS AND ECONOMIC FACTORS IN THE CREDIT ANALYSIS

The last analytical factor is the economic health or viability of the bond issuer or specific project financed by the bond proceeds. The economic factors cover a variety of concerns. When analyzing general obligation bond issuers, one should look at the specific budgetary and debt characteristics of the issuer, as well as the general economic environment. For project-financing, or enterprise, revenue bonds, the economics are limited primarily to the ability of the project to generate sufficient charges from the users to pay the bondholders. These are known as *pure revenue bonds*.

For revenue bonds that rely not on user charges and fees but instead on general purpose taxes and revenues, the analysis should take basically the same approach as for the general obligation bonds. For these bonds, the taxes and revenues diverted to the bondholders would otherwise go to the state's or city's general fund.

As an example, the bonds of the New York State Municipal Assistance Corporation for the City of New York Bonds (MAC), secured by general New York City sales taxes and annual state-aid appropriations, were structured to appear as pure revenue bonds, but in essence they were not. They incorporated a bond structure created to bail out New York City from severe budget deficits. The creditworthiness of the bond was tied to that of the underlying jurisdiction, which has had portions of its taxing powers and general fund revenues diverted to secure this new revenue-type bailout bond. Besides looking at the revenue features, the investor therefore must look at the underlying jurisdiction. These MACs were first issued in 1975 and refunded through the years. It should be noted that in 2004, the MACs were refunded, now with "Sales Tax *Asset* Receivable Corporation" bonds and stretched out to 2033 for paying off operating deficits of the 1960s.

For General Obligation Bonds

For general obligation bonds, the economic concerns include questions in four specific areas: debt burden, budget soundness, tax burden, and the overall economy.

Debt Burden

In relation to the debt burden of the general obligation bond issuer, some of the more important concerns include the determination of the total amount of debt outstanding and to be issued that is supported by the general taxing powers of the issuer as well as by earmarked revenues.

For example, general obligation bonds issued by school districts in New York State are general obligations of the issuer and are also secured by state-aid payments due the issuer. If the issuer defaults, the bondholder can go to the state comptroller and be paid from the next state-aid payment due the local issuer. An example of another earmarked-revenue general obligation bond is the State of Illinois General

Obligation Transportation, Series A Bond. For these state general obligations, debt service is secured by gasoline taxes in the state's transportation fund.

Key debt ratios that reveal the burden on local taxpayers include determining the per capita amount of general obligation debt as well as the per capita debt of the overlapping or underlying general obligation bond issuers. Other key measures of debt burden include determining the amounts and percentages of the outstanding general obligation bonds as well as the outstanding general obligation bonds of the overlapping or underlying jurisdictions to real estate valuations. These numbers and percentages can be compared with most recent year medians, as well as with the past history of the issuer, to determine whether the debt burden is increasing, declining, or remaining relatively stable.

In addition to the general obligation bonds outstanding, the debt of the general obligation bond issuer could include leases, certificates of participation (COPs), appropriation, and "moral obligation" bonds.

Additionally, the amount of the unfunded pension liabilities should be determined. What is the difference between the expected assets of the public employee system at current annual contribution rates, the future benefits to be paid out, and if the issuer has a reasonable plan to eliminate the unfunded liability? Can pension benefits unilaterally be reduced by the local governments? Such steps are allowed in some jurisdictions, but not in others. An example of the latter is New York State, where the state constitution prevents the reduction of pension benefits once they are granted. Therefore, the unfunded pension liabilities of local governments in New York must be taken much more seriously than in states where such guarantees do not exist.

Still another special debt figure that came into the forefront in the first decade of the twenty-first century involves the actuarially determined costs of providing health care for retirees. These are postemployment benefits. In many jurisdictions they are not legally mandatory and are paid on a pay-as-you-go basis. There are usually strong political groups such as unions and the retirees themselves that support these benefits. In some jurisdictions the potential size of this liability is greater than the outstanding general obligation bonds.

For purposes of determining the special debt figure—which represents the potential liability in a worst-case environment—the COPs, appropriation and lease obligations, the moral obligations, the unfunded pension liabilities, and the retiree health care costs should be shown and broken out.

Budgetary Soundness

Concerning the budgetary operations and budgetary soundness of the general obligation bond issuer, some of the more important questions include how well the issuer over at least the previous five years has been able to maintain balanced budgets and fund reserves. How dependent is the issuer on short-term debt to finance annual budgetary operations? How have increased demands by residents for costly social services been handled? That is, how frugal is the issuer? How well have the public-employee unions been handled? They usually lobby for

higher salaries, liberal pensions, and other costly fringe benefits. Clearly, it is undesirable for the pattern of dealing with the constituent demands and public-employee unions results in raising taxes and drawing down nonrecurring budget reserves. Last, another general concern in the budgetary area is the reliability of the budget and accounting records of the issuer. Are interfund borrowings reported? Who audits the books?

It should be noted that by 2011, e-commerce and Internet usage were steadily growing among American consumers. Many states, counties, and city governments over the past 50 years have derived substantial revenues from sales taxes that are not always applied to Internet sales. In some jurisdictions, over 20% of an issuer's revenues may come from local sales taxes. How the growth of the Internet affects this revenue source is uncertain at this time, but at some future date could be a significant negative for the budgets of at least some issuers as well as for their bonds secured by these taxes.

Tax Burden

Concerning the tax burden, it is important to learn two things initially. First, what are the primary sources of revenue in the issuer's general fund? Second, how dependent is the issuer on any one revenue source? If the general obligation bond issuer relies increasingly on a property tax, wage and income taxes, or sales tax to provide the major share of financing for annually increasing budget appropriations, taxes could quickly become so high as to drive businesses and people away. Many larger northern states and cities with their relatively high income, sales, and property taxes appear to be experiencing this phenomenon. Still another concern is the degree of dependency of the issuer on intergovernmental revenues, such as federal or state revenue sharing and grants-in-aid, to finance its annual budget appropriations. Political coalitions on the state and federal levels that support these financial transfer programs are not permanent and could undergo dramatic change very quickly. Therefore, a general obligation bond issuer that currently has a relatively low tax burden but receives substantial amounts of intergovernmental monies should be reviewed carefully by the investor. If it should occur that the aid monies are reduced, as has been occurring under many federal and state programs, certain issuers primarily may increase their taxes instead of reducing their expenditures to conform to the reduced federal grants-in-aid.

Overall Economy

The fourth and last area of general obligation bond analysis concerns the issuer's overall economy. For local governments, such as counties, cities, towns, and school districts, key items include learning the annual rate of growth of the full value of all taxable real estate for the previous 10 years and identifying the 10 largest taxable properties. What kinds of business or activity occur on the respective properties? What percentage of the total property tax base do the 10 largest properties represent? What has been the building permit trend for at least the

previous five years? What percentage of all real estate is tax-exempt, and what is the distribution of the taxable ones by purpose (such as residential, commercial, industrial, railroad, and public utility)? Last, who are the five largest employers? Concerning the final item, communities that have one large employer are more susceptible to rapid adverse economic change than communities with more diversified employment and real estate bases. For additional information that reveals economic health or decline, one must determine whether the population of the community over the previous 10 years has been increasing or declining by age and income and how the monthly and yearly unemployment rates compare with the national averages, as well as with the previous history of the community.

For state governments that issue general obligation bonds, the economic analysis should include many of the same questions applied to local governments. In addition, the investor should determine on the state level the annual rates of growth for the previous five years of personal income and retail sales and how much the state has had to borrow from the Federal Unemployment Trust Fund to pay unemployment benefits. This last item is particularly significant for the long-term economic attractiveness of the state because employers in states with large federal loans in arrears may be required to pay increased unemployment taxes to the federal government.

For Revenue Bonds

Airport Revenue Bonds

For airport revenue bonds, the economic questions vary according to the type of bond security involved. There are two basic security structures.

The first type of airport revenue bond is one based on traffic-generated revenues that result from the competitiveness and passenger demand of the airport. The financial data on the operations of the airport should come from audited financial statements going back at least three years. If a new facility is planned, a feasibility study prepared by a recognized consultant should be reviewed. The feasibility study should have two components: (1) a market and demand analysis to define the service area and examine demographic and airport use trends and (2) a financial analysis to examine project operating costs and revenues.

Revenues at an airport may come from landing fees paid by the airlines for their flights, passenger facility charges (PFCs), concession fees paid by restaurants, shops, newsstands, and parking facilities, and from airline apron and fueling fees.

Also, in determining the long-term economic viability of an airport, the investor should determine whether or not the wealth trends of the service area are upward, whether the airport is dependent on tourism or serves as a vital transfer point, whether passenger enplanements and air cargo handled over the previous five years have been growing, whether increased costs of jet fuel and airport safety would make other transportation such as trains and automobiles more attractive in that particular region, and whether the airport is a major domestic hub for an airline,

which could make the airport particularly vulnerable to route changes caused by schedule revisions and changes in airline corporate management.

The second type of airport revenue bond is secured by a lease with one or more airlines for the use of a specific facility such as a terminal or hangar. The lease usually obligates them to make annual payments sufficient to pay the expenses and debt service for the facility. For many of these bonds, the analysis of the airline lease is based on the credit quality of the lessee airline. Whether or not the lease should extend as long as the bonds are outstanding depends on the specific airport and facility involved. For major hub airports, it may be better not to have long-term leases because without leases, fees and revenues can be increased as the traffic grows, regardless of which airline uses the specific facility. Of course, for regional or startup airports, long-term leases with trunk (i.e., major airline) carriers are preferred.

After 9/11, air travel suffered a unique temporary downturn. While air travel remains an essential service, after the terrorist attacks, the analysis of the credit quality of airports and airlines with related bankruptcy issues has undergone increased scrutiny.

Charter School Bonds

Charter school bonds are for publicly funded private schools that offer more institutional and academic flexibility than local public schools. State-aid funding usually follows the student who goes from a traditional public school to a charter school. Bond proceeds go for capital improvements.

Some important credit questions to ask include: (1) How long is the charter granted by the state or local school district, and is it renewable? (2) What is the charter school enrollment history—is it growing? (3) Does the school serve a specialty academic niche, or is it just relieving overcrowding at local public schools? (4) What is its reputation in the community? (5) Is there competition? (6) Is there a waiting list? (7) Is the school prudently run with cash reserves, i.e., how many days of cash are on hand? and (8) How reasonable are the operating and maintenance expenses in relationship to the revenues and debt service requirements?

Continuing Care Retirement Community Bonds

A continuing care retirement community (CCRC) provides housing accommodations and health-related services to elderly persons, typically for the duration of their lifetimes. These nonprofit organizations finance a portion of development and operating costs by issuing bonds secured by the entrance fees and monthly fees paid by their residents. The potential demand for a CCRC is largely affected by the number of elderly persons in the nearby area with qualifying assets and income, the presence and proximity of competitor facilities, and the strength of the local real estate market. Other important considerations include whether advance fee deposits are partially or fully refundable, the experience of the general contractor and management, the background of the sponsor, and the amount of cash reserves on hand. A careful analysis of the data and assumptions of any feasibility study formed is essential.

Dedicated Tax-Backed and Structured/Asset-Backed Bonds

More recently, states and local governments have issued increasing amounts of bonds where the debt service is to be paid from so-called dedicated revenues such as sales taxes, tobacco settlement payments, fees, and penalty payments. Many are structured to mimic the asset-backed bonds that are common in the taxable market. The "assets" providing the security for the municipal bonds are the "dedicated" revenues instead of credit card receivables, home equity loans, and auto loan repayments that are commonly used to secure the taxable asset-backed bonds.

Additionally, the municipal bonds are usually subject to some form of annual legislative appropriation and result from statutes specially created to pledge the identified taxes and revenues and allow for the bond sales. In good economic times many investors as well as the rating agencies tend to blur the credit distinctions between these bonds and the issuer's own general obligation bonds. In fact, many such bonds carry higher credit ratings than the underlying general obligation bonds because the "coverage" on the former appears to be so high. In most instances, the general obligation bonds are legally backed by specific state constitutional provisions, whereas, the dedicated tax and structured/asset-backed bonds are recent legislative creations and have not been tested yet in stressful budgetary, economic, and political environments.

Higher Education Bonds

Debt is often issued by institutions of higher education to finance the costs of building/renovating facilities or purchasing land for expansion. These bonds are secured by revenues of the given project, student charges, and/or a general obligation of the college or university. An investor in higher education bonds should carefully consider the following: (1) Is student demand for the issuing institution strong and growing? (2) Does the school have flexibility to increase tuition or enrollment if needed? (3) How experienced are senior management and the board of trustees? (4) What are the school's various sources of funding? (5) What is the endowment level and how is it trending? (6) How well does the school manage expenses and repay its debts? (7) What is the physical condition of school facilities? and (8) Are there any construction or project-specific risks?

Highway Revenue Bonds

There are generally two types of highway revenue bonds. The bond proceeds of the first type are used to build specific revenue-producing facilities such as toll roads, bridges, and tunnels. For these pure enterprise revenue bonds, the bondholders have claims to the revenues collected through the tolls. The financial soundness of the bonds depends on the ability of the specific projects to be self-supporting. Proceeds from the second type of highway revenue bond generally are used for public highway improvements, and the bondholders are paid by earmarked revenues such as gasoline taxes, automobile registration payments, and driver's license fees.

Concerning the economic viability of a toll revenue bond, the investor should ask a number of questions.

1. What is the traffic history, and how inelastic is the demand? Toll roads, bridges, and tunnels that provide vital transportation links are clearly preferred to those that face competition from interstate highways, toll-free bridges, or mass transit.
2. How well is the facility maintained? Has the issuer established a maintenance reserve fund at a reasonable level to use for such repair work as road resurfacing and bridge painting?
3. Does the issuer have the ability to raise tolls to meet covenant and debt reserve requirements without seeking approvals from other governmental actors such as state legislatures and governors? In those few cases where such approvals are necessary, the question of how sympathetic these other power centers have been in the past in approving toll-increase requests should be asked.
4. What is the debt-to-equity ratio? Some toll authorities have received substantial nonreimbursable federal grants to help subsidize their costs of construction. This, of course, reduces the amount of debt that has to be issued.
5. What is the history of labor-management relations, and can public-employee strikes substantially reduce toll collections?
6. When was the facility constructed? Generally, toll roads financed and constructed in the 1960s tend to be in better financial condition because the cost of financing was much less.
7. If the facility is a bridge that could be damaged by a ship and made inoperable, does the issuer have adequate use-and-occupancy insurance?

Those few toll revenue bonds that have defaulted have done so because of either unexpected competition from toll-free highways and bridges, poor traffic projections, or substantially higher than projected construction costs. An example of one of the few defaulted bonds is the West Virginia Turnpike Commission's Turnpike Revenue Bonds, issued in 1952 and 1954 to finance the construction of an 88-mile expressway from Charleston to Princeton, West Virginia. The initial traffic-engineering estimates were overly optimistic, and the construction costs came in approximately $37 million higher than the original budgeted amount of $96 million. Because of insufficient traffic and toll collections, between 1956 and 1979 the bonds were in default. By the late 1970s with the completion of various connecting cross-country highways, the turnpike became a major link for interstate traffic. The bonds became self-supporting in terms of making interest coupon payments. It was not until 1989 that all the still-outstanding bonds were finally redeemed.

More recently, a new group of start-up toll roads has been financed with municipal bonds. The revenue projections for several roads turned out to be overly optimistic. Some have had to draw on the debt reserves. Others have had to be restructured and even defaulted. Examples include the Santa Rosa Bay Bridge Authority in Florida, the Southern Connector Toll Road in South Carolina, and the San Joaquin Toll Road in California.

Concerning the economics of highway revenue bonds that are not pure enterprise type but instead are secured by earmarked revenues, such as gasoline taxes, automobile registration payments, and driver's license fees, the investor should ask the following questions:

- Are the earmarked tax revenues based on state constitutional mandates, such as the state of Ohio's Highway Improvement Bonds, or are they derived from laws enacted by state legislatures, such as the state of Washington's Chapters 56, 121, and 167 Motor Vehicle Fuel Tax Bonds? A constitutional pledge is usually more permanent and reliable.
- What has been the coverage trend of the available revenues to debt service over the previous 10 years? Has the coverage been increasing, stable, or declining?
- If the earmarked revenue is a gasoline tax, is it based on a specific amount per gallon of gasoline sold or as a percentage of the price of each gallon sold? With greater conservation and more efficient cars, the latter tax structure is preferred because it is not as susceptible to declining sales of gasoline and because it benefits directly from any increased gasoline prices at the pumps.
- What has been the history of statewide gasoline consumption through recessions and oil shocks?

Hospital Revenue Bonds

Two unique features of hospitals make the analysis of their debt particularly complex and uncertain. The first concerns their sources of revenue, and the second concerns the basic structure of the institutions themselves.

During the past 40 years, the major sources of revenue for most hospitals have been (1) payments from the federal (Medicare) and combined federal-state (Medicaid) hospital reimbursement programs, and (2) appropriations made by local governments through their taxing powers. It is not uncommon for hospitals to receive at least half of their annual revenues from these sources. How well the hospital management markets its service to attract more private-pay patients and commercial insurers, and how conservatively it budgets for the governmental reimbursement payments are key elements for distinguishing weak from strong hospital bonds.

Particularly for community-based hospitals (as opposed to teaching hospitals affiliated with medical schools), a unique feature of their financial structure

is that their major financial beneficiaries, physicians, have no legal or financial liabilities if the institutions do not remain financially viable over the long term. An example of the problems that can be caused by this lack of liability is found in the story of the Sarpy County, Nebraska, Midlands Community Hospital Revenue Bonds. These bonds were issued to finance the construction of a hospital three miles south of Omaha, Nebraska, that was to replace an older one located in the downtown area. Physician questionnaires prepared for the feasibility study prior to the construction of the hospital indicated strong support for the replacement facility. Many doctors had used the older hospital in downtown Omaha as a backup facility for a larger nearby hospital. Unfortunately, once the new Sarpy hospital opened in 1976, many physicians found that the new hospital could not serve as a backup because it was 12 miles further away from the major hospital than the old hospital had been. Because these physicians were not referring their patients to the new Sarpy hospital, it was soon unable to make bond principal payments and was put under the jurisdiction of a court receiver.

The preceding factors raise long-term uncertainties about many community-based hospitals, but certain key areas of analysis and trends reveal the relative economic health of hospitals that already have revenue bonds outstanding. The first area is the liquidity of the hospital as measured by the ratio of dollars held in current assets to current liabilities. In general, a five-year trend of high values for the ratio is desirable because it implies an ability by the hospital to pay short-term obligations and thereby avoid budgetary problems. Days cash on hand is an important measure as well. The second indicator is the ratio of long-term debt to equity, as measured in the unrestricted end-of-year fund balance. In general, the lower the long-term debt to equity ratio, the stronger the finances of the hospital are. The third indicator is the actual debt service coverage of the previous five years, as well as the projected coverage. The fourth indicator is the annual bed-occupancy rates for the previous five years. The fifth is the percentage of physicians at the hospital who are professionally approved (board certified), their respective ages, and how many of them use the hospital as their primary institution.

For new or expanded hospitals, much of the preceding data are provided to the investor in the feasibility study. One item in particular that should be determined for a new hospital is whether the physicians who plan to use the hospital actually live in the area to be served by the hospital. Because of its importance in providing answers to these questions, the feasibility study must be prepared by reputable, experienced researchers.

Housing Revenue Bonds

For housing revenue bonds, the economic and financial questions vary according to the type of bond security involved. There are two basic types of housing revenue bonds, each with a different type of security structure. One is the housing revenue bond secured by *single-family* mortgages, and the other is the housing revenue bond secured by mortgages on *multifamily* housing projects.

Concerning single-family housing revenue bonds, the strongly secured bonds usually have five characteristics:

- The single-family home loan bonds are collateralized by GNMA, FNMA, or FHLMC; or the loans are insured by the Federal Housing Administration (FHA), Department of Veteran Affairs (VA), or an acceptable private mortgage insurer or its equivalent. If the individual home loans are not insured, then they should have a loan-to-value ratio of 80% or less. Prior to 2007, many bonds had acceptable private mortgage insurance.
- If the conventional home loans have less than 100% primary mortgage insurance coverage, or are not backed by federal collateral, an additional 5% to 10% mortgage-pool insurance policy or its equivalent may be required.
- In addition, there is a mortgage reserve fund equal at least to 1% of the mortgage portfolio outstanding.
- The issuer of the single-family housing revenue bonds is in a region of the country that has stable or strong economic growth as indicated by increased real estate valuations, personal income, and retail sales, as well as low unemployment rates.
- State housing finance agency support.

In the 1970s, state agency issuers of single-family housing revenue bonds assumed certain prepayment levels in structuring the bond maturities. In recent years, most issuers have abandoned this practice but investors should review the retirement schedule for the single-family mortgage revenue bonds to determine whether or not the issuer has assumed large, lump-sum mortgage prepayments in the early year cash-flow projections. If so, how conservative are the prepayment assumptions, and how dependent is the issuer on the prepayments to meet the annual debt service requirements? Of course, while the focus of this chapter is on credit analysis, the investor should be aware that extraordinary redemptions of these bonds can occur from prepayments on the mortgages.

It should be noted that since the mid-1990s, issuers have adopted structures similar to those in the taxable mortgage-backed securities market that incorporate prepayment assumptions. In tax-exempt single-family housing bonds, these are usually the planned amortization class (PAC) structures.

State issuing agencies usually have professional in-house staffs that closely monitor the home mortgage portfolios, whereas the local issuers do not. Finally, many state issuing agencies have accumulated substantial surplus funds over the years that can be viewed as an additional source of bondholder protection.

For multifamily housing revenue bonds, there are four specific, although overlapping, security structures. The first type of multifamily housing revenue bond is one in which the bonds are secured by federally insured mortgages. Usually, the federal insurance covers all but the difference between the outstanding bond principal and collectible mortgage amount (usually 1%), and all but the *nonasset* bonds

(i.e., bonds issued to cover issuance costs and capitalized interest). The attractiveness of the federal insurance is that it protects the investor against bond default within the limitations outlined. The insurance protects the bondholders regardless of whether the projects are fully occupied and generating rental payments.

The second type of multifamily housing revenue bond is one in which the federal government subsidizes, under the HUD Section 8 program, all annual costs (including debt service) of the project not covered by tenant rental payments. Under Section 8, the eligible low-income and elderly tenants pay only 15% to 30% of their incomes for rent. Because the ultimate security comes from the Section 8 subsidies, which normally escalate annually with the increased cost of living in that particular geographic region, the bondholder's primary risks concern the developer's ability to complete the project, find tenants eligible under the federal guidelines to live in the project, and then maintain high occupancy rates for the life of the bonds. The investor should carefully review the location and construction standards used in building the project, as well as the competency of the project manager in selecting tenants who will take care of the building and pay their rents. In this regard, state agencies that issue Section 8 bonds usually have stronger in-house management experience and resources for dealing with problems than do the local development corporations that have issued Section 8 bonds. It should be noted that the federal government has eliminated appropriations for new Section 8 projects. Since 1995, the federal government has restricted automatic rent increases under the Section 8 program. This has introduced financial pressure.

The third type of multifamily housing revenue bond is one in which the ultimate security for the bondholder is the ability of the project to generate sufficient monthly rental payments from the tenants to meet the operating and debt service expenses. Some of these projects may receive governmental subsidies (such as interest-cost reductions under the federal Section 236 program and property tax abatements from local governments), but the ultimate security is the economic viability of the project. Key information includes the location of the project, its occupancy rate, whether large families or the elderly will primarily live in the project, whether or not the rents necessary to keep the project financially sound are competitive with others in the surrounding community, and whether or not the project manager has a proven record of maintaining good service and of establishing careful tenant selection standards.

A fourth type of multifamily housing revenue bond is one that includes some type of private credit enhancement to the underlying real estate. These credit enhancements can include guarantees or sureties of an insurance company, securitization by Fannie Mae (Federal National Mortgage Association or FNMA), or a bank letter-of-credit.

Other financial features desirable in all multifamily housing bonds include a debt service reserve fund, which should contain an amount of money equal to the maximum annual debt service on the bonds, a mortgage reserve fund, and a capital repair and maintenance fund.

Another feature of many multifamily housing revenue bond programs, particularly those issued by state housing agencies, is the state moral obligation pledge. Several state agencies have issued housing revenue bonds that carry a potential state liability for making up deficiencies in their one-year debt service reserve funds, should any occur. In most cases, if a drawdown of the debt reserve occurs, the state agency must report the amount used to its governor and state budget director. The state legislature, in turn, may appropriate the requested amount, although there is no legally enforceable obligation to do so. Bonds with this makeup provision are called *moral obligation bonds*.

The moral obligation provides a state legislature with permissive authority—*not mandatory authority*—to make an appropriation to the troubled state housing agency. Therefore, the analysis should determine (1) whether the state has the budgetary surpluses for subsidizing the housing agency's revenue bonds, and (2) whether there is a consensus within the executive and legislative branches of that particular state's government to use state general fund revenues for subsidizing multifamily housing projects.

Industrial Revenue Bonds

Generally, industrial revenue bonds are issued by state and local governments on behalf of individual corporations and businesses. The security for the bonds usually depends on the economic soundness of the particular corporation or business involved. If the bond issue is for a subsidiary of a larger corporation, one question to ask is whether or not the parent guarantees the bonds. Is it obligated only through a lease, or does it not have any obligation whatsoever for paying the bondholders? If the parent corporation has no responsibility for the bonds, then the investor must look very closely at the operations of the subsidiary in addition to those of the parent corporation.

For companies that have issued publicly traded common stock, operating data are readily available in the quarterly (10-Q) and annual (10-K) financial reports that must be filed with the Securities and Exchange Commission. For privately held companies, financial data are more difficult to obtain.

In assessing the economic risk of investing in an industrial revenue bond, another question to ask is whether the bondholder or the trustee holds the mortgage on the property. Although holding the mortgage is not an important economic factor in assessing either hospital or low-income multifamily housing bonds in which the properties have very limited commercial value, it can be an important strength for the holder of industrial development revenue bonds. If the bond is secured by a mortgage on a property of a major retailer, or an industrial facility such as a warehouse, the property location and resale value of the real estate may provide some protection to the bondholder, regardless of what happens to the company that issued the bonds. Of course, the investor always should avoid possible bankruptcy situations regardless of the economic attractiveness of the particular piece of real estate involved. The reason is that the bankruptcy process usually involves years of litigation and numerous court hearings, about which no investor should want to be concerned.

Land-Secured "Dirt" Bonds

Public infrastructure costs associated with new development projects on raw land are often financed by land-secured bonds, also known as "dirt" bonds. Revenue from the additional tax or assessment placed on the properties benefitting from these improvements is the primary security for the bondholders. Additional security is provided by the ability of the sponsoring governmental entity to commence foreclosure or tax sales if property owners are delinquent on their taxes or assessments. Important credit factors to consider include: (1) Is the development's location, demographics, and competitive position favorable? (2) Does the developer possess sufficient experience and financial resources? (3) Is there a debt service reserve and other funds, and how are they funded? (4) Is the lien created by the tax/assessment fixed or variable, and what is the resulting debt service coverage provided? (5) Is the value of the land relative to the outstanding liens sufficient to discourage property owners from walking away?

Lease-Rental Bonds

Lease-rental bonds usually are structured as revenue bonds, and annual payments, paid by a state or local government, cover all costs including operations, maintenance, and debt service. It should be noted that many Certificate of Participation Bonds, or COPs, are similar in security structure in that they too are dependent on the annual legislative appropriation process. The public purposes financed by these bond issues include public office buildings, fire houses, police stations, university buildings, mental health facilities, and highways, as well as office equipment and computers. In some instances, the payments may come from student tuition, patient fees, and earmarked tax revenues, and the state or local government is not legally obligated to make lease-rental payments beyond the amount of available earmarked revenues. However, for many lease-rental bonds, the underlying lessee state, county, or city is to make payment from its general fund subject to annual legislative appropriation. For example, the Albany County, New York, Lease Rental South Mall Bonds were issued to finance the construction of state office buildings. Although the bonds were technically general obligations of Albany County, the real security came from the annual lease payments made by the State of New York. These payments were appropriated annually. For such bonds, the basic economic and financial analysis should follow the same guidelines as for general obligation bonds.

Public Power Revenue Bonds

Public power revenue bonds are issued to finance the construction of electrical generating plants. An issuer of the bonds may construct and operate one power plant, buy electric power from a wholesaler and sell it retail, construct and operate several power plants, or join with other public and private utilities in jointly financing the construction of one or more power plants. This last arrangement is known as a joint-power financing structure. Although there are revenue bonds that can claim the revenues of a federal agency (e.g., the Washington Public Power

Supply System's Nuclear Project No. 2 Revenue Bonds, which if necessary could claim the revenues of the Bonneville Power Administration), and others may require the participating underlying municipal electric systems to pay the bondholders whether or not the plants are completed and operating, the focus here is how the investor determines which power projects will be financially self-supporting without these backup security features.

There are at least five major questions to ask when evaluating the investment soundness of a public power revenue bond:

- Does the bond issuer have the authority to raise its electric rates in a timely fashion without going to any regulatory agencies? This is particularly important if substantial rate increases are necessary to pay for new construction or plant improvements.
- How diversified is the customer base among residential, commercial, and industrial users?
- Is the service area growing in terms of population, personal income, and commercial/industrial activity so as to warrant the electrical power generated by the existing or new facilities?
- Are rates competitive with neighboring IOUs?
- What are the projected and actual costs of power generated by the system, and how competitive are they with other regions of the country? Power rates are particularly important for determining the long-term economic attractiveness of the region for industries that are large energy users.
- How diversified is the fuel mix? Is the issuer dependent on one energy source such as hydro dams, oil, natural gas, coal, or nuclear fuel?

Concerning electrical generating plants fueled by nuclear power, the aftermath of the Three Mile Island nuclear accident in 1979 has resulted in greater construction and maintenance reviews and costly safety requirements prompted by the Federal Nuclear Regulatory Commission (NRC). The NRC oversees this industry. In the past, although nuclear power plants were expected to cost far more to build than other types of power plants, it also was believed that once the generating plants became operational, the relatively low fuel and maintenance costs would more than offset the initial capital outlays. However, with the increased concern about public safety brought about by the Three Mile Island accident, repairs and design modifications are now expected to be made even after plants begin to operate. Of course, this increases the ongoing costs of generating electricity and reduces the attractiveness of nuclear power as an alternative to the oil, gas, and coal fuels.

Public-Private Partnerships

Privatization is a form of municipal financing where a private company pays a large payment to operate, and often build or improve, a governmental asset

(e.g., usually toll roads). The purchaser issues debt to help finance this large upfront cost, and the operating revenues are pledged to repay bondholders. The bonds issued are referred to as private-placement partnership bonds (PPP). Important questions to ask about these bonds are: (1) What is the length of the concession agreement? (2) How are prices or tolls set? (3) Does the governmental entity share in any revenue? (4) Are there any noncompete provisions? (5) What levels of maintenance, capital expenditures, and service are required? (6) What are the conditions and repercussions for nonperformance? and (7) What are the assumptions and conclusions of any feasibility study performed?

Tobacco Revenue Bonds

Some tobacco bonds are solely secured by revenues in the Master Settlement Agreement (MSA) annually paid to states by cigarette companies. Important credit issues include: (1) The credit quality of the cigarette companies making the annual payments; (2) the consumption assumptions used in sizing the original bond issue, i.e., the degree of leveraging used; (3) current consumption trends and their impacts on cash-flows and debt coverage; and (4) the status of the various court cases.

Tribal Casino Bonds

Native American governments in general finance the construction of their casino gaming facilities by issuing debt. Tribal casino bonds derive their revenues from the gaming operations of these facilities. Given the limited diversity of the revenue streams and the lack of hard collateral assets, evaluating the future viability and profitability of the new gaming facility is essential, including analysis of the relevant demographics, competitive factors, and quality of casino management. Buyers should also assess the financial strength, governance structure, and development project expertise of the issuing tribal entity. Other issues to consider include whether the cash trapping and debt service reserve fund features of the issued debt are sufficient, any gaming compact and revenue sharing arrangements with state governments, and potential regulatory changes. It should be noted that a U.S. Federal District court in Wisconsin recently ruled in favor of a tribal bond issuer seeking to abandon its payment obligation, claiming the related indenture breached federal tribal gaming regulations. This case was under appeal.

Water and Sewer Revenue Bonds

Water and sewer revenue bonds are issued to provide for a local community's basic needs and as such are not usually subject to general economic changes. Because of the vital utility services performed, their respective financial structures are usually designed to have the lowest possible user charges and still remain financially viable. Generally, rate covenants requiring that user charges cover operations, maintenance, and approximately 1.2 times annual debt service and reserve requirements are most desirable. On the one hand, a lower rate covenant provides a smaller margin for unanticipated slow collections or increased operating and plant maintenance costs caused by inflation. On the other hand,

rates that generate revenues more than 1.2 times the annual debt service and reserve requirements could cause unnecessary financial burdens on the users of the water and sewer systems.

A useful indication of the soundness of an issuer's operations is to compare the water or sewer utility's average quarterly customer billings to those of other water or sewer systems. Assuming that good customer service is given, the water or sewer system that has a relatively low customer billing charge generally indicates an efficient operation and therefore strong bond-payment prospects.

Key questions for the investor to ask include the following:

- Has the bond issuer, through local ordinances, required mandatory water or sewer connections? Also, local board of health directives against well water contamination and septic tank usage can often accomplish the same objective as the mandatory hookups.
- Does the issuer have to comply with an EPA consent decree and thereby issue significant amounts of bonds?
- What is the physical condition of the facilities in terms of plant, lines, and meters, and what capital improvements are necessary for maintaining the utilities as well as for providing for anticipated community growth?
- For water systems in particular, it is important to determine if the system has water supplies in excess of current peak and projected demands. An operating system at less than full utilization is able to serve future customers and bring in revenues without having to issue additional bonds to enlarge its facilities.
- What is the operating record of the water or sewer utility for the previous five years?
- If the bond issuer does not have its own distribution system but instead uses other participating local governments that do, are the charges or fees based on the actual water flow drawn (for water revenue bonds) and sewage treated (for sewer revenue bonds) or on gallonage entitlements?
- For water revenue bonds issued for agricultural regions, what crop is grown? An acre of oranges or cherries in California will provide the grower with more income than will an acre of corn or wheat in Iowa.
- For expanding water and sewer systems, does the issuer have a record over the previous two years of achieving net income equal to or exceeding the rate covenants, and will the facilities to be constructed add to the issuer's net revenues?
- Has the issuer established and funded debt and maintenance reserves to deal with unexpected cash-flow problems or system repairs?
- Does the bond issuer have the power to place tax liens against the real estate of those who have not paid their water or sewer bills? Although

the investor would not want to own a bond for which court actions of this nature would be necessary, the legal existence of this power usually provides an economic incentive for water and sewer bills to be paid promptly by the users.

Additional bonds should be issued only if the need, cost, and construction schedule of the facility have been certified by an independent consulting engineer and if the past and projected revenues are sufficient to pay operating expenses and debt service. Of course, for a new system that does not have an operating history, the quality of the consulting engineer's report is of the upper-most importance.

RED FLAGS FOR THE INVESTOR

In addition to the areas of analysis just described, certain red flags, or negative trends, suggest increased credit risks.

For General Obligation Bonds

For general obligation bonds, the signals that indicate a decline in the ability of a state, county, town, city, or school district to function within fiscally sound parameters include the following:

- Declining property values and increasing delinquent taxpayers
- An annually increasing tax burden relative to other regions
- An increasing property tax rate in conjunction with a declining population
- Declines in the number and value of issued permits for new building construction
- Actual general fund revenues consistently falling below budgeted amounts
- Increasing end-of-year general fund deficits
- Budget expenditures increasing annually in excess of the inflation rate
- The unfunded pension liabilities are increasing
- General obligation debt increasing while property values are stagnant
- Declining economy as measured by increased unemployment and declining personal income

For Revenue Bonds

For revenue bonds, the general signals that indicate a decline in credit quality include the following:

- Annually decreasing coverage of debt service by net revenues
- Use of debt reserve and other reserves by the issuer

- Growing financial dependence of the issuer on unpredictable federal and state-aid appropriations for meeting operating budget expenses
- Chronic lateness in supplying investors with annual audited financials
- Unanticipated cost overruns and schedule delays on capital construction projects
- Frequent or significant rate increases
- Deferring capital plant maintenance and improvements
- Excessive management turnovers
- Shrinking customer base
- New and unanticipated competition

INFORMATION SOURCES FOR THE ANALYST

The Official Statement

An official statement describing the issue and the issuer is prepared for new offerings. A preliminary official statement is issued prior to the final official statement. These statements are known as the OS and POS. These statements provide potential investors with a wealth of information. The statements contain basic information about the amount of bonds to be issued, maturity dates, coupons, the use of the bond proceeds, the credit ratings, a general statement about the issuer, and the name of the underwriter and members of the selling group. Much of this information can be found on the cover page or in the first few pages of the official statement. It also contains detailed information about the security and sources of payments for the bonds, sources and uses of funds, debt service requirements, relevant risk factors, issuer's financial statements, a summary of the bond indenture, relevant agreements, notice of any known existing or pending litigation, the bond insurance policy specimen (if insured), and the form of opinion of bond counsel. The official statement contains most of the information an investor will need to make an informed and educated investment decision.

Continuing Disclosure Under Rule 15c2-12

Rule 15c2-12, which took effect in 1995, required dealers to determine that issuers before issuing new municipal bonds made arrangements to disclose in the future financial information *at least* annually as well as notices of the occurrence of any of 11 "material event notices" as specified in the rule. By 2011, the amended rule contained 14 material event notices. Also by 2011, the annual report and notices of material events are to be filed with the Municipal Securities Rulemaking Board (MSRB), in an electronic format as prescribed by the MSRB. The MSRB designated its Electronic Municipal Market Access system (EMMA), found at http://emma.msrb.org as the sole repository for such disclosure filings.

It should be noted that many issuers, such as hospitals, toll roads, and CCRCs provide unaudited interim information to bondholders on a quarterly and even a monthly basis.

The National Federation of Municipal Analysts

The National Federation of Municipal Analysts (NFMA) was established in 1983 and by 2011 had a membership of 1,000 municipal professionals, drawing in part from the institutional investors in municipal bonds who advocated increased and timely information for investors. By 2011, its committees have developed detailed disclosure guidelines and risk factors in municipal securities ranging from specific credit sectors to swap structures. They are recommended for municipal bond issuers to use in providing ongoing financial and operating information to investors and analysts. The web site is www.nfma.org.

The Governmental Standards Accounting Board

The Governmental Standards Accounting Board (GSAB) is a nonprofit organization that sets generally accepted accounting standards (GAAP) for state and local governments. Established in 1984 it provides detailed guidelines. For many years it has improved financial reporting standards in reports of state and local governments that are used by analysts, auditors, and other users. By improving the transparency of state and local government accounting, it helps prevent issuers from obfuscating budget deficits and long-term liabilities that in the past had resulted in budgetary disasters and bond defaults. The web site is http://gasb.org.

KEY POINTS

- The five categories of inquiry when analyzing the creditworthiness of a general obligation, tax-backed, or pure revenue bond are (1) legal documents and opinions, (2) politics/management, (3) underwriter/financial advisor, (4) general credit indicators and economics, and (5) red flags, or danger signals.
- From the perspective of the bondholder, the legal opinions and document reviews should be the ultimate security provisions. The reason is that if all else fails, the bondholder may have to go to court to enforce his or her security rights. The relationship of the legal opinion to the analysis of municipal bonds for both general obligation and revenue bonds is the following: (1) the attorney should check to determine whether the issuer is indeed legally able to issue the bonds; (2) the attorney is to see that the issuer has properly prepared for the bond sale by enacting the various required ordinances, resolutions, and trust indentures and without violating any other laws and regulations;

and (3) the attorney is to certify that the security safeguards and remedies provided for the bondholders and pledged by either the bond issuer or third parties are actually supported by federal, state, and local government laws and regulations.

- Before purchasing a municipal bond the investor should investigate whether the issuer's officials (1) are conscientious public servants with clearly defined public goals; (2) have a history of successful management of public institutions; and (3) have demonstrated commitments to professional and fiscally stringent operations. In addition, it is important to scrutinize closely (and possibly avoid) issuers in highly charged and partisan environments in which conflicts chronically occur between political parties or among political factions or personalities.
- Indicators of the quality of the investment are (1) who the issuer selected as its financial advisor, if any; (2) its principal underwriter if the bond sale was negotiated; and (3) its financial advisor if the bond issue came to market competitively. It is also useful to find out who was the underwriter for the issue.
- An analytical factor to consider in assessing the creditworthiness of an issue is the economic health or viability of the bond issuer or specific project financed by the bond proceeds. The economic factors cover a variety of concerns. When analyzing general obligation bond issuers, the specific budgetary and debt characteristics of the issuer, as well as the general economic environment should be investigated. For project-financing, or enterprise, revenue bonds, the economics are limited primarily to the ability of the project to generate sufficient charges from the users to pay the bondholders. In the case of revenue bonds that rely not on user charges and fees, but instead on general purpose taxes and revenues, the analysis should take basically the same approach as for the general obligation bonds. For these bonds, the taxes and revenues diverted to the bondholders would otherwise go to the state's or city's general fund.

CHAPTER
FORTY-FIVE

CREDIT-RISK MODELING

TIM BACKSHALL
Chief Credit Derivatives Strategist
Credit Derivatives Research Ltd.

KAY GIESECKE, PH.D.
Assistant Professor of Management Science and Engineering
Stanford University

LISA GOLDBERG, PH.D.
Executive Director of Research
MSCI and
Adjunct Professor of Statistics
University of California at Berkeley

Since the turn of the century, we have seen many theoretical developments in the field of credit-risk research. In view of the large-scale changes in market conditions, the entry of more sophisticated market participants, and the increase in complexity of investable assets, most of the research has focused on pricing of corporate debts. But many of these models have failed to describe real-world phenomena such as credit-spreads realistically. This practitioner-oriented chapter attempts to describe the history and future of modeling credit-risk and valuation of credit-risky assets.

Credit-risk is the distribution of financial losses owing to unexpected changes in the credit quality of the counterparty in a financial agreement. Examples range from agency downgrades to failure to service debt to liquidation. Credit-risk pervades virtually all financial transactions. The distribution of credit losses is complex. At its center is the probability of default, by which we mean any type of failure to honor a financial agreement. To estimate the probability of default, we need to specify

- A model of investor uncertainty
- A model of the available information and its evolution over time
- A model definition of the default event.

However, default probabilities alone are not sufficient to price credit-sensitive securities. We need, in addition,

- A model for the risk-free interest rate
- A model of recovery on default
- A model of the premium investors require as compensation for bearing systematic credit-risk

The credit premium maps actual default probabilities to market-implied probabilities that are embedded in market prices. To price securities that are sensitive to the credit-risk of multiple issuers and to measure aggregated portfolio credit-risk, we also need to specify

- A model that links defaults of different entities

There are three main quantitative approaches to analyzing credit. In the *structural approach,* we make explicit assumptions about the dynamics of a firm's assets, its capital structure, and its debt and share holders. A firm defaults if its assets are insufficient according to some measure. In this situation, a corporate liability can be characterized as an option on the firm's assets. The *reduced-form approach* is silent about why a firm defaults. Instead, the dynamics of default are given exogenously through a default rate, or intensity. In this approach, prices of credit-sensitive securities can be calculated as if they were default-free using an interest rate that is the risk-free rate adjusted by the intensity. The *incomplete-information approach* combines the structural and reduced-form models. While avoiding their difficulties, it picks the best features of both approaches: the economic and intuitive appeal of the structural approach and the tractability and empirical fit of the reduced-form approach.

In this chapter we review the three approaches in the context of the multiple facets of credit modeling that were just mentioned. Our goal is to provide a concise overview and a guide to the large and growing literature on credit-risk.[1]

STRUCTURAL CREDIT MODELS

The basis of the structural approach, which goes back to Black and Scholes[2] and Merton,[3] is that corporate liabilities are contingent claims on the assets of a firm. The market value of the firm is the fundamental source of uncertainty driving credit-risk.

Classical Approach

Consider a firm with market value V, which represents the expected discounted future cash-flows of the firm. The firm is financed by equity and a zero-coupon bond with face value K and maturity date T. The firm's contractual obligation is to repay the amount K to the bond investors at time T. Debt covenants grant bond investors absolute priority: if the firm cannot fulfill its payment obligation, then bondholders immediately will take over the firm.

1. A more mathematical introduction can be found in Kay Giesecke, "Credit-Risk Modeling and Valuation: An Introduction," in David Shimko (ed.), *Credit-Risk: Models and Management,* Vol. 2 (London: Riskbooks, 2004).
2. Fischer Black and Myron Scholes, "The Pricing of Options and Corporate Liabilities," *Journal of Political Economy* 81 (1973), pp. 81–98.
3. Robert C. Merton, "On the Pricing of Corporate Debt: The Risk Structure of Interest Rates," *Journal of Finance* 29 (1974), pp. 449–470.

EXHIBIT 45–1

Default Interpretation in the Classical Approach

Exhibit 45–1 shows several possible paths of firm value. Default occurs if the firm value at maturity is less than the face value of the debt K. The particular path the firm value has taken does not matter here; only the firm value at T is important. The probability of default therefore is equal to the probability that firm value is below debt face value at maturity. To calculate this probability, we make assumptions about the distribution of firm value at debt maturity. The standard assumption is that firm value is log-normally distributed. The probability of default then is given as the area under the log-normal firm value density between 0 and face value, as shown in the graph. This probability can be calculated explicitly in terms of K, the current firm value $V(0)$, the volatility of firm value, the growth rate of firm value and T.

Assuming that the firm can neither repurchase shares nor issue new senior debt, the payoffs to the firm's liabilities at debt maturity T are as summarized in Exhibit 45–2. If the asset value $V(T)$ exceeds or equals the face value K of the bonds, the bondholders will receive their promised payment K, and the shareholders will get the remaining $V(T) - K$. However, if the value of assets $V(T)$ is

EXHIBIT 45–2

Payoffs at Maturity in the Classical Approach

Event Description	Assets	Debt	Equity
No default	$V(T) \geq K$	K	$V(T) - K$
Default	$V(T) < K$	$V(T)$	0

EXHIBIT 45–3

Term Structure of Credit-Spreads, Varying Asset Volatility, in the Classical Approach

less than K, the ownership of the firm will be transferred to the bondholders, who lose the amount $K - V(T)$. Equity is worthless because of limited liability.

Summarizing, the value of the bond is equivalent to that of a portfolio composed of a default-free loan with face value K maturing at time T and a short European put position on the assets of the firm with strike K and maturity T. The value of the equity is equivalent to the payoff of a European call option on the assets of the firm with strike K and maturity T. Pricing equity and credit-risky debt thus reduces to pricing European options.

The credit-spread is the difference between the yield on a defaultable bond and the yield on an otherwise equivalent default-free zero bond. It gives the excess return demanded by bond investors to bear the potential default losses. The credit-spread is a function of maturity T, asset volatility (the firm's business risk), the initial leverage ratio $K/V(0)$, and risk-free rates.

Letting initial leverage be 80% and risk-free rates be 6%, in Exhibit 45–3 we plot the model term structure of credit-spreads for varying asset volatilities. We see clearly that as asset volatility (business risk) rises, then so does the spread required by the market to compensate for the risk of default. Other noticeable traits of this graph are the rapid fall to zero spreads at short maturities and the more pronounced hump-shaped curve as volatility rises higher.

First-Passage Approach

In the classical approach, firm value can dwindle to almost nothing without triggering default. This is unfavorable to bondholders, as noted by Black and

EXHIBIT 45–4

Default in the First-Passage Approach

Cox.[4] Bond indenture provisions often include safety covenants that give bond investors the right to reorganize a firm if its value falls below a given barrier.

First-passage time models generalize the classical model such that a default can occur not only at maturity of the debt contract but also at any point of time. They assume that default happens if the firm value V hits a specified default barrier D. The default barrier in general can be a stochastic process, as is the firm value. For tractability reasons, however, one often works with a simple time-dependent, nonstochastic barrier specification, or just a constant barrier.

Suppose that the default barrier D is a constant between zero and the initial firm value—this is reasonable because we would expect liabilities to be nonnegative and less than current assets. Then the default time is more realistically defined as when the value of the firm crosses below the default barrier. In other words, firms can default at times other than debt maturity. This relaxation of the European nature of the default event in the classical approach provides some more realistic behavior.

Exhibit 45–4 shows several possible paths of firm value and a constant default barrier D. Suppose for the moment that D is equal to the face value of the firm's debt. Default occurs if the firm value falls, at any time before the horizon T, below the default barrier. As shown, different firm-value paths correspond to different default times. Unlike the classical model discussed earlier, here the entire path the firm value follows is relevant. Firm-value paths that imply survival in the classical approach can

4. Fischer Black and John C. Cox, "Valuing Corporate Securities: Some Effects of Bond Indenture Provisions," *Journal of Finance* 31 (1976), pp. 351–367.

imply default in the first-passage approach. Therefore, the first-passage approach implies higher probabilities of default than the classical approach.

The probability of default is given by the probability that the minimum firm value at the horizon $M(T)$ is lower than the barrier D. In order to calculate this probability, we make an assumption about the distribution of future firm values, as in the classical approach. This determines also the distribution of the minimum firm value at the horizon. With log-normal firm values, this distribution is inverse gaussian. The default probability is given as the area under the inverse gaussian density curve between 0 and the default barrier D.

We consider the payoff to investors in the firm's liabilities. For simplicity, we assume that the default barrier is equal to the face value of firm debt. If the firm value never fell below the barrier over the term of the bond, then bond investors receive the bond's face value K and equity investors would receive the remaining $V(T) - K$. However, if the firm falls below the barrier at some point during the bond's term, then the firm defaults. In this case the firm stops operating, bond investors take over its remaining assets, and equity investors receive nothing.

Therefore, the equity position is equivalent to that of a down-and-out call on firm assets with strike equal to the face value of the debt, barrier level equal to the default barrier, and maturity equal to debt maturity. The value of the debt is given as the difference between firm value and equity value. Pricing equity and credit-risky debt thus reduces to pricing European barrier options.

We consider the credit-spread implied by a first-passage model in Exhibit 45–5. We assume that the default barrier is constant and equal to the face value of the bonds. We set leverage equal to 60% and risk-free rates to 6%,

EXHIBIT 45–5

Term Structure of Credit-Spreads, Varying Asset Volatility, in the First-Passage Model

as in Exhibit 45–3. We assume that in the event of default, bond investors recover a fraction of 50% of their initial investment.

With increasing maturity T, the spread asymptotically approaches zero. This is at odds with empirical observation; for many firms, spreads tend to increase with increasing maturity, reflecting the fact that uncertainty is greater in the distant future than in the near term. This discrepancy follows from two model properties: the firm value grows at a positive (risk-free) rate, and the capital structure is constant and assumed known with certainty. We can address this issue by assuming that the total debt grows at a positive rate or that firms maintain some target leverage ratio as in Collin-Dufresne and Goldstein.[5] A critical insight from this plot is that the level of spreads in the first-passage model is much higher and much more realistic than in the classical model. This is due to the fact that default probabilities are higher in the first-passage approach, as we discussed earlier.

Dependent Defaults

Credit-spreads of different issuers are correlated through time. Two patterns are found in time series of spreads. The first is that spreads vary smoothly with general macroeconomic factors in a correlated fashion. This means that firms share a common dependence on the economic environment, which results in cyclic correlation between defaults. The second relates to the jumps in spreads: we observe that these are often common to several firms or even entire markets. This suggests that the sudden large variation in the credit-risk of one issuer, which causes a spread jump in the first place, can propagate to other issuers as well. The rationale is that economic distress is contagious and propagates from firm to firm. A typical channel for these effects are borrowing and lending chains. Here the financial health of a firm also depends on the status of other firms as well.

We want to incorporate these two default correlation mechanisms into the structural approach to credit. To introduce cyclic correlation, it is natural to assume that firm values of several firms are correlated through time. This corresponds to common factors driving asset returns. We consider the simplest case with two firms whose firm values are log normal. Our definition of default follows the classical approach.

Exhibit 45–6 illustrates the situation. The axes show the marginal asset return distributions of the two firms. Individual asset returns are normally distributed, hence the bell shape. Individual returns are modeled through a linear factor model, which represents systematic and firm-specific risk. Systematic risk is modeled by a common latent factor X, which drives the systematic variation in the asset returns of both firms. The sensitivity of a firm's return to this common factor controls the asset correlation across firms. This asset correlation drives the default correlation between firms.

5. Pierre Collin-Dufresne and Robert Goldstein, "Do Credit-Spreads Reflect Stationary Leverage Ratios?" *Journal of Finance* 56 (2001), pp. 1929–1958.

EXHIBIT 45–6

Illustrative Example of Structural-Based Joint Default Modeling

The elliptical shapes represent lines of equal joint asset value probability. The shaded area on the bottom left illustrates the joint default probability, as defined by the area under which issuer 1's asset value is below its default barrier and issuer 2 is below its default barrier.

Asset correlation captures the dependence of firms on common economic factors in a natural way. Modeling default contagion effects is much more difficult. A straightforward idea is to consider a jump-diffusion model for firm value. We would stipulate that a downward jump in the value of a given firm triggers subsequent jumps in the firm values of other firms with some probability. This would correspond to the propagation of economic distress. This approach is difficult, however, because of the lack of closed-form results on the joint distribution of firms' historical asset lows. This is what we need to calculate the probability of joint default.

A more successful attempt is to introduce interaction effects through the default barriers D_i. Suppose that the barrier is random and depends on the firm's liquidity state, which, in turn, depends on the default status of the firm's counterparties. If a firm's liquidity reserves are stressed owing to a payment default of a counterparty, it finances the loss by issuing more debt. This increases the default,

barrier: the firm is now more likely to default, all else being equal. With no counterparty defaults the default barrier remains unaffected. This model allows a closed-form approximation of the credit portfolio loss distribution.

Credit Premium

Issuers of credit-sensitive securities share a common dependence on the economic environment. It follows that aggregated credit-risk cannot be diversified away. This undiversifiable or systematic risk commands a premium, which compensates risk-averse investors for assuming credit-risk.

The credit premium is empirically well documented. Its importance relates to the uses of a quantitative credit model. As a default probability forecasting tool, a credit model must reflect the historical default experience. As a tool for pricing credit-sensitive securities, it must fit observed market prices. To make use of both market data and historical default data in the calibration and application of a credit model, we need to understand the relationship between actual defaults and defaultable security prices.

Here the risk premium comes into play: it maps the actual likelihood of default $p(T)$ into the market-implied likelihood of default $q(T)$ that is embedded in security prices.

We examine the difference between the two using a simple example in Exhibit 45–7. We consider a one-period market with two securities, a risk-free bond paying 10 and trading at 10 (risk-free rates are zero) and a defaultable bond trading at 5 that pays 20 in case of no default and zero in case the issuer defaults by the end of the trading period.

EXHIBIT 45–7

Real-World versus Market-Implied Probability of Default

Suppose that the actual probability of default is $p = 0.5$ (50%, or a coin flip). This is, however, not the probability the market uses for pricing the bond: it would lead to a price of $p.20 + (1 - p).0 = 10$, which is double the price at which the bonds are actually trading. At this price, risk-averse investors would rather put their money into the risk-free bond that costs 10 as well, unless they get a discount as compensation for the default risk. The market requires a discount of 5, and the corresponding price reflects the market-implied probability of default q, which satisfies $5 = (1 - q).20$. This yields $q = 0.75$ (75% probability of default), which is bigger than the actual probability of default $p = 0.5$.

To account for risk aversion in calculating the expected payoff of the defaultable bond, the market puts more weight on the unfavorable states of the world in which the firm defaults. In the structural credit models with firm value dynamics as described previously and constant risk-free rates, the situation is only a little more complicated.

In the absence of arbitrage opportunities, the credit-risk premium α is uniquely determined through market prices of credit-sensitive securities such as equity or debt and is measured as the excess return on firm assets over the risk-free return per unit of firm risk measured in terms of asset volatility. If the market is risk-averse, then α is positive: investors in credit-risky firm assets require a return that is higher than the risk-free return. The excess return on any credit-sensitive security is given by its volatility times α.

Calibration

The calibration of a quantitative credit model is closely related to its use. To price single-name credit-sensitive securities using a structural model, we need to calibrate the risk-free rate, the asset volatility, the asset value, the face value of the debt, the default barrier, and the maturity of the debt. The default barrier is relevant only in the first-passage approach. To use the model to forecast actual default probabilities, we need to calibrate additionally the growth rate of firm assets or, equivalently, the credit-risk premium α. In a multiple-firm setting we need to estimate asset correlations in addition to the single-name parameters.

Firm values are not observable. The goal is to estimate the parameters of the firm-value process based on equity prices, which can be observed for public firms. Risk-free interest rates can be estimated from default-free Treasury bond prices via standard procedures. We bypass estimation of face value and maturity of firm debt from balance-sheet data, which is nontrivial given the complex capital structure of firms. In practice, these parameters often are fixed ad hoc, as some average of short- and long-term debt, for example. We introduce a more reasonable solution to this problem later.

We consider the classical approach, as briefly discussed earlier. Given equity prices and equity volatilities, Jones, Mason, and Rosenfeld and many others suggest

to back out asset values and asset volatilities by numerically solving a system of two equations.[6] The first equation relates the equity price to asset value, time, and asset volatility and follows from the Black-Scholes pricing function for a European call with strike K and maturity T. The second equation relates the equity price to asset and equity volatility, the delta of equity, and asset value. This relation is obtained from applying Ito's formula to the first equation.

We can use these two equations to "translate" a time series of equity values into a time series of asset values and volatilities. As for the equity volatility, we can use the empirical standard deviation of equity returns or a true forecasting model such as Barra Equity Risk models. Given a time series of asset returns, the empirical growth rate yields an estimate of the market price of credit-risk. The estimate of the firm growth rate, however, is very poor: it is based on two asset-return observations only.

Further, given the asset-return time series of several firms, asset correlation can be estimated. Alternatively, we can introduce a linear-factor model for normally distributed asset returns that expresses the idea that firms share a common dependence on general economic factors. This is similar to the idea we discussed earlier.

Can We Predict the Future?

To a certain extent, users of structural models implicitly assume that they can. In structural models, firm value is the single source of uncertainty that drives credit-risk. Investors observe the distance of default as it evolves over time. If the firm value has no jumps, this implies that the default event is not a total surprise. There are "predefault events" that announce the default of a firm. In the first-passage approach, we can think of a predefault event as the first time assets fall dangerously close to the default barrier (see Exhibit 45–8).

This has significant implications for the fitting of structural models to market prices. First, since default can be anticipated, the model price of a credit-sensitive security converges continuously to its recovery value. Second, the model credit-spread tends to zero with time to maturity going to zero.[7] Quite telling in this regard are the credit-spreads implied by the classical and first-passage approaches (see Exhibits 45–3 and 45–5). Both properties are at odds with intuition and market reality. Market prices do exhibit surprise downward jumps on default. Even for very short maturities in the range of weeks, market credit-spreads remain positive. This indicates that investors do have substantive short-term uncertainty about defaults, in contrast to the predictions of the structural models.

EXHIBIT 45–8

Announcing the Default Timing by a Sequence of "Predefault" Events in the First-Passage Approach

REDUCED-FORM CREDIT MODELS

Reduced-form models were developed in the 1990s.[8] Here we assume that default occurs without warning. This means that investors face short-term credit-risk, which is absent from the structural models discussed previously. This is a desirable model property because it allows us to fit the model to market credit-spreads.

Default Intensity

The rate at which default occurs is called the *default intensity,* and we denote it by λ. We can think of the *intensity* at time t as the conditional probability that default will happen immediately, given that the firm has escaped default by t. As such, it describes the short-term credit-risk investors face.

The intensity is the central ingredient of all reduced-form models. It is modeled as a (nonnegative) stochastic process under the market-implied probability. The time evolution of the intensity reflects changes in the instantaneous default probability of a firm. The intensity model is calibrated from market prices

8. See Philippe Artzner and Freddy Delbaen, "Default Risk Insurance and Incomplete Markets," *Mathematical Finance* 5 (1995), pp. 187–195; Robert A. Jarrow and Stuart M. Turnbul, "Pricing Derivatives on Financial Securities Subject to Credit-Risk," *Journal of Finance* 50 (1995), pp. 53–86; and Darrell Duffie and Kenneth J. Singleton, "Modeling Term Structures of Defaultable Bonds," *Review of Financial Studies* 12 (1999), pp. 687–720.

of credit-sensitive securities issued by the firm. There is a one-to-one relation between the intensity and the corresponding default probabilities.

We give two simple but useful specifications for the intensity and the corresponding default probabilities.

- *Example 1*. Suppose that λ is a constant. Then default is a Poisson arrival, and the default time is exponential with parameter λ. The default probability thus is given by $q(T) = 1 - \exp(-\lambda T)$.
- *Example 2*. Suppose that $\lambda = \lambda(t)$ is a deterministic function of time t. Then default is an inhomogeneous Poisson arrival. A simple but useful parameterization that is frequently used is the assumption that $\lambda(t)$ is stepwise defined over finite periods across the spread curve—these stepwise constants can be calibrated easily from market data.

These examples constitute only a small sample of possible parameterizations of the default intensity. There are many more choices, often borrowed from the classical term-structure models based on the short-term interest rate. This is motivated by the close analogy of defaultable term-structure models and classical, nondefaultable term-structure models to which we turn next.

Valuation

The description of the default dynamics through the market-implied default intensity λ leads to tractable valuation formulas. Below we describe several different specifications of these formulas corresponding to different units for the value recovered by investors at default.

We consider a zero-coupon bond paying 1 at maturity T if there is no default and a fraction $0 < R < 1$ of an equivalent (face value 1, maturity T) but default-free bond at default if default occurs before maturity T. This recovery specification is often called *equivalent recovery*. Given the market-implied probability of default $q(T)$, and assuming that R is a constant, the present value of the bond can be written as $\exp(-rT) - \exp(-rT)(1 - R)q(T)$. Here, r is the constant risk-free rate of interest. Thus the value of the bond is the value of an otherwise equivalent risk-free bond minus the present value of the default loss $(1 - R)$. If the intensity is constant (Example 1) and recovery is zero, we obtain for the bond price today $\exp[-(r + \lambda)T]$. This means that the value of the defaultable bond is calculated as if the bond were risk-free by using a default-adjusted discount rate. The new discount rate is the sum of the risk-free rate r and the intensity λ. This parallel between pricing formulas for defaultable bonds and otherwise equivalent default-free bonds is one of the best features of reduced-form models.

An alternative recovery model is called *fractional recovery of predefault market value*. Here it is assumed that the bond recovers a fraction $0 < R < 1$ of the market value of the bond just prior to default. If the recovery rate and the intensity are constant (Example 1 above), we obtain the following convenient formula for

the bond price: $\exp\{-[r + \lambda(1 - R)]T\}$. This is the value of a zero-recovery defaultable bond when the issuer's default intensity is "thinned" to $\lambda(1 - R)$. The intuition behind this is as follows. Suppose that the bond defaults with intensity λ. At default, the bond becomes worthless with probability $(1 - R)$, and its value remains unchanged with probability R. Clearly, the predefault value of the bond is not changed by this way of looking at default. Consequently, for pricing, we can ignore the "harmless" default, which occurs with intensity λR. We then price the bond as if it had zero recovery and a default intensity of $\lambda(1 - R)$. The fractional-recovery pricing formula is then implied by the formula for equivalent recovery.

The results for the valuation of more complex credit-sensitive securities are analogous, and in the general case, a credit-sensitive security can be valued as if it were not sensitive to credit-risk by using an adjusted rate for discounting payoffs.

We take a closer look at the credit-spreads implied by reduced-form models. In the simple case where recovery is zero and some technical conditions are satisfied, we can show that short-term credit-spreads tend to λ and not zero. This should be contrasted with the structural models, where the spread goes to zero with time to maturity going to zero. In the reduced-form models, the default event is unpredictable; it comes without warning. There is always short-term uncertainty about the default event, for which investors demand a premium. This premium, expressed in terms of yield, is given by the intensity.

The unpredictability of default has another important consequence. In line with empirical observation, the model price of a credit-sensitive security will drop abruptly to its recovery value on default. This is in direct conflict with the structural models considered earlier, in which the price converges to its default contingent value and remains there as equity value drops to zero.

Default Correlation

In the reduced-form approach we can introduce cyclical default correlation by assuming that firms' default intensities are correlated through time. Similarly to the structural models of correlated default, we can introduce systematic and firm-specific factors that drive the intensities of firms. The sensitivity of a firm with respect to the systematic factors controls the intensity correlation across firms. This intensity correlation drives the dependence between firm defaults. Joint default probabilities can be calculated by observing that the intensity of the first default in a portfolio of names is the sum of the default intensities of the individual issuers in the portfolio.

Reduced-form models provide a flexible framework for modeling the dynamics of multiple-issuer credit-risk. However, calibration of the model to market variables is not trivial because of the scarcity of default data and the need to model a large number of parameters simultaneously. There are also studies that argue that the approach can be problematic for other reasons.

Taking account of contagious default correlation in the reduced-form approach is not an easy exercise. The idea is that there are correlated jumps in firms'

default intensities corresponding to the correlated jumps we observe in credit-spreads. A variant of this assumes that there are marketwide events that can trigger joint defaults.[9] Another variant assumes that the default intensity of a firm depends explicitly on the default status of related counterparty firms in the market.[10] To avoid running into a circularity problem, one can suppose that only the default of designated "primary" firms has an effect on other "secondary" firms.

While Jarrow and Yu[11] focus on the pricing of credit-sensitive securities in the presence of contagion effects, it is difficult to calculate joint default probabilities and portfolio loss distributions within this approach. As Davis and Lo[12] and Giesecke and Weber[13] show, one can obtain tractable closed-form characterizations of loss distributions at the cost of more restricting assumptions that relate to the homogeneity of firms and the symmetry in their counterparty relations.

Calibration

Reduced-form models typically are formulated directly under the market-implied probability. This suggests that we calibrate directly from market prices of various credit-sensitive securities. One often uses liquid debt prices or credit default swap spreads, although Jarrow argues that equity is a good candidate as well.[14] Depending on the characteristics of the calibration security, it may be necessary to make parametric assumptions about the recovery process as well. With fractional recovery and zero bonds, for example, the problem is to choose the parameters of the adjusted short rate model $r + \lambda(1 - R)$ such that model bond prices best fit observed market prices.

Here one can either parameterize the adjusted short rate directly or specify the component processes separately. With a separate specification, identification problems may arise because only the product $\lambda(1 - R)$ enters the pricing formula just described. In general, in the estimation problem one can draw from the experience related to nondefaultable term-structure models given the close analogy to reduced-form defaultable models.[15]

INCOMPLETE-INFORMATION CREDIT MODELS

For the purpose of measuring default risk, neither the structural nor the reduced-form model explicitly accounts for the fact that investors rely on information that is imperfect. The framework described in this section addresses this issue directly by giving a common perspective on reduced-form and structural models. This perspective leads to previously unrecognized hybrid models that incorporate the best features of both traditional approaches while avoiding their shortcomings.

Incomplete-information credit models were introduced by several researchers.[16] Giesecke and Goldberg[17] describe a structural reduced-form hybrid default model based on incomplete information. This model, hereafter denoted I^2, is a first-passage time model: it assumes that a firm defaults when its value falls below a barrier. All first-passage time models require descriptions of both firm value and a default barrier. What distinguishes the I^2 model from traditional first-passage time models as we described them earlier is that it assumes that investors do not know the default barrier. The importance of modeling uncertainty about the default barrier is highlighted by high-profile scandals at firms such as Enron, Tyco, and WorldCom. In these cases, public information led to poor estimates of the default barrier.

Both the expected default barrier and the uncertainty around it can be calibrated to available information in the I^2 model. Imagine that a firm is believed to be in good financial health but that a particular analyst thinks otherwise. The analyst can increase the forecasts to line up with her views by raising the expected value of the barrier. She also can adjust the variance of the default barrier to the level of her confidence in reported levels of the firm's liability.

Other incomplete-information models can be envisioned. We can think of a situation where we cannot observe firm values or receive noisy or lagged firm-value information. Another situation is when we are uncertain about both firm values and the default barrier.

With incomplete information, default becomes a surprise event. It cannot be anticipated any more, as it can in the traditional first-passage models. It follows that investors face short-term credit-risk as in the reduced-form models. With short-term uncertainty, the model prices generated by the incomplete-information models provide an excellent fit to market prices. In particular, model prices are consistent with the jumps in prices observed around the default announcement. Model spreads are consistent with the nonzero short-term spreads observed in the credit markets. Exhibit 45–9 shows the term structure of credit-spreads implied

EXHIBIT 45–9

Term Structure of Credit-Spreads, Varying Asset Volatility, in the I^2 Model

by the I^2 model, assuming risk-free rates of 6%. Strictly positive short spreads reflect the compensation for the short-term credit-risk that investors face.

Giesecke and Goldberg calibrate the I^2 model from market data and further analyze its empirical properties. In particular, the I^2 model output is compared empirically with a traditional first-passage model. Two main conclusions can be drawn. The I^2 model reacts more quickly because it takes direct account of the entire history of public information rather than just current values. Furthermore, the I^2 model predicts positive short spreads for firms in distress. The traditional first-passage model always predicts that short spreads are zero.

Dependent Defaults

Since incomplete-information models are based on the structural approach, we can model cyclical default correlation through firm-value correlation.

Contagious default correlation arises very naturally with incomplete information. Consider the I^2 model. With defaults of firms arriving over time, we learn about the unobserved default barriers of the surviving firms.[18] This means that we update the distribution we put on a firm's default barrier with the information we extract from the unanticipated defaults of counterparty firms and reassess firms' default probabilities. The situation in which we do

18. This is discussed in detail in Kay Giesecke, "Correlated Default with Incomplete Information," *Journal of Banking and Finance* 28 (2004), pp. 1521–1545.

EXHIBIT 45–10

Firm Value in the Incomplete-Information Model

not directly observe firm values is very similar.[19] In both scenarios, the "contagious" jumps in credit-spreads we observe in credit markets are implied by informational asymmetries.

Credit Premium

The credit-risk premium is the mapping between the actual probability and the market-implied probability. To understand the structure of the premium, we examine the dynamics of firm value and corporate liabilities in the I^2 model. We argued earlier that thanks to the unpredictability of default, prices of credit-sensitive claims including firm equity and debt drop precipitously at default. Empirical observation shows that equity drops to near zero. This makes sense because equity holders have no stake in the firm after default. The value of the bonds is diminished by bankruptcy costs, which is described by some fractional recovery R.

Consequently, firm value, which is equal to the sum of equity and debt values, also drops at default. This is shown in Exhibit 45–10. Therefore, there are two sources of uncertainty related to firm value:

- The first is the diffusive uncertainty.
- The second is the uncertainty associated with the downward jump at default.

19. This is analyzed in Pierre Collin-Dufresne, Robert Goldstein, and Jean Helwege, "Are Jumps in Corporate Bond Yields Priced: Modeling Contagion via the Updating of Beliefs," working paper, Carnegie Mellon University, 2002.

Giesecke and Goldberg show that in the I^2 model the credit-risk premium can be decomposed into two components, which correspond to the two sources of uncertainty:[20]

- The diffusive risk premium α compensates investors for the diffusive uncertainty in firm value. As in the traditional structural models, it is realized as a change to the drift term in firm-value dynamics.
- The default event risk premium β is not present in the traditional structural models. It compensates investors for the jump uncertainty in firm value and is realized as a change to the default probability. Driessen[21] empirically confirms that this event risk premium is a significant factor in corporate bond returns.

Giesecke and Goldberg demonstrate that the assumption of no arbitrage is realized in the mathematical relationships among α, β, the recovery rate assumed by the market, and the coefficients of the price processes of traded securities. The price processes depend explicitly on the leverage ratio, so the premia α and β do as well. As Giesecke and Goldberg discuss,[22] this violates an important condition for the Modigliani and Miller theorem.[23] The I^2 model therefore is not consistent with the Modigliani-Miller theorem. It provides a new way to measure the deviation of real markets from the idealized markets in which the Modigliani-Miller theorem holds.

The structure of the incomplete-information risk premium is analogous to the risk premium in reduced-form models considered in El Karoui and Martellini[24] and Jarrow, Lando, and Yu.[25] The diffusive premium related to the firm-value process corresponds to a premium for diffusive risk in the default intensity process. The event risk premium is analogous to the default event risk premium in intensity-based models. However, in the incomplete-information setting it is defined in the general reduced-form context where an intensity need not exist.

Calibration

There is a lively debate in the literature concerning which data should be used to calibrate credit. Jarrow[26] points to a division between structural and reduced-form modelers on this issue. Traditionally, structural models are fit to equity markets and reduced-form models are fit to bond markets. Jarrow argues that the equity and bond data can be used in aggregate to calibrate a credit model, and he gives a recipe for doing this in a reduced-form setting.

Giesecke and Goldberg[27] apply reasoning similar to that of Jarrow to calibrate the I^2 model. The estimation procedure makes use of historical default rates in conjunction with data from equity, bond, and credit default swap markets. Huang and Huang[28] give empirical evidence that structural models yield more plausible results if calibrated to both kinds of data. Importantly, the physical and market-implied probabilities are fit simultaneously. The output of the calibration includes estimates of the risk premium, market-implied recovery, model security prices, and physical probabilities of default.

One issue addressed in Giesecke and Goldberg[29] is the relationship between model and actual capital structures. In the classical setting, equity is a European option, with strike price and date equal to the face value and maturity of a zero bond. This model fits market data only to the extent that firm debt can be represented adequately as a zero bond. Giesecke and Goldberg make use of the flexibility imparted by incomplete information to give a more realistic picture of equity. Specifically, equity is a down-and-out call with a stochastic strike price. This approach sidesteps the intractable problem of describing a complex capital structure in terms of a single face value and maturity date.

KEY POINTS

- Credit-risk is the distribution of financial losses owing to unexpected changes in the credit quality of the counterparty in a financial agreement.
- Estimating probability of default requires the specification of a (1) model of investor uncertainty, (2) model of the available information and its evolution over time, and (3) model definition of the default event.
- Because default probabilities alone are not sufficient to price credit-sensitive securities, it is necessary to have a (1) model for the risk-free

26. Jarrow, "Default Parameter Estimation Using Market Prices."
27. Kay Giesecke, and Lisa Goldberg, "Calibrating Credit with Incomplete Information," working paper, Cornell University, 2004.
28. Jay Huang and Ming Huang, "How Much of the Corporate-Treasury Yield Spread Is Due to Credit-Risk?" working paper, Stanford University, 2003.
29. Giesecke and Goldberg, "Calibrating Credit with Incomplete Information."

interest rate, (2) model of recovery on default, and (3) model of the premium investors require as compensation for bearing systematic credit-risk.

- The credit premium maps actual default probabilities to market-implied probabilities that are embedded in market prices.
- In order to price securities that are sensitive to the credit-risk of multiple issuers and measure aggregated portfolio credit-risk, a model that links defaults of different entities must be specified.
- The three main quantitative approaches to analyzing credit are the structural approach, the reduce-form approach, and the incomplete-information approach.
- The basis of the structural approach is the Black-Scholes-Merton framework, in which corporate liabilities are contingent claims on the assets of a firm. The market value of the firm is the fundamental source of uncertainty driving credit-risk. The structural approach makes explicit assumptions about the dynamics of a firm's assets, its capital structure, and its debt and share holders. A firm defaults if its assets are insufficient according to some measure. In this situation, a corporate liability can be characterized as an option on the firm's assets.
- First-passage time structural models generalize the classical model such that a default can occur not only at maturity of the debt contract, but also at any point of time.
- Credit-spreads of different issuers are correlated through time and must be incorporated into a credit-risk model. Two patterns are found in time series of spreads: (1) spreads vary smoothly with general macroeconomic factors in a correlated fashion, and (2) there are jumps in spreads that are common to several firms or even entire markets.
- Reduced-form models assume that default occurs without warning. That is, this approach is silent about why a firm defaults. Instead, the dynamics of default are given exogenously through a default rate, or intensity. In this approach, prices of credit-sensitive securities can be calculated as if they were default-free using an interest rate that is the risk-free rate adjusted by the intensity. Default intensity is the rate at which defaults occur.
- The incomplete-information approach combines the best features of the structural and reduced-form models while at the same time avoiding the shortcomings of the two models. More specifically, it combines the economic and intuitive appeal of the structural approach and the tractability and empirical fit of the reduced-form approach.

Risk management is an integral part of the investment process. Risk models are central to this practice, allowing managers to quantify and analyze the risk embedded in their portfolios. Risk models provide managers with insight into the different sources of risk in a portfolio, helping them to control their exposures and understand the contributions of different portfolio components to total risk. They help portfolio managers in their decision-making process by providing answers to important questions such as: How does my long-duration exposure affect portfolio risk? Does my underweight in diversified financials hedge my overweight in banks? Risk models are also widely used in various other areas such as in portfolio construction, performance attribution, and scenario analysis.

In this chapter we introduce linear multifactor risk models and illustrate how they can be helpful for the analysis of the risk of fixed income portfolios. We review the major sources of risk in fixed income securities and introduce a set of appropriate risk factors. We also present several applications of risk models for

The authors would like to thank Bruce Phelps and Andy Sparks for their valuable comments.

effective portfolio construction and management. In Chapter 47 we will go through a detailed risk model report of a specific portfolio and highlight the information and insights it can provide to a portfolio manager.

MOTIVATION AND STRUCTURE UNDERLYING FIXED INCOME MULTIFACTOR RISK MODELS

In this section, we discuss the motivation and structure behind fixed income multifactor risk models.

Let us assume that a portfolio manager wants to estimate and analyze the volatility of a large portfolio of fixed income instruments. A straightforward idea would be to compute the volatility of the historical returns of the portfolio and use this measure to forecast future volatility. However, this framework does not provide any insight into the relationships between different securities in the portfolio or the major sources of risk. For instance, it does not assist a portfolio manager interested in diversifying a portfolio or constructing a portfolio that has better risk-adjusted performance. Additionally, the characteristics of a fixed income portfolio change substantially over time, for instance, as instruments mature or are subject to credit events.

Instead of estimating the portfolio volatility using historical portfolio returns, a portfolio manager could utilize a different strategy. The portfolio return is a function of individual instrument returns (e.g., Treasury securities, corporate bonds, credit derivatives, municipal bonds, interest rate swaps, and so on) and the market weights of these securities in the portfolio. Using this, the forecasted volatility of the portfolio (σ_P^f) can be computed as a function of the weights (w) and the covariance matrix (Σ_S) of the instrument returns in the portfolio:

$$\sigma_P^f = \sqrt{w^T \times \Sigma_S \times w}$$

where the superscript T denotes a matrix transpose. This covariance matrix can be decomposed into individual instrument volatilities and the correlations between returns.

Volatilities measure the riskiness of individual instrument returns, and correlations represent the relationships between the returns of different instruments. By measuring these correlations and volatilities, the portfolio manager can gain insight into her portfolio related to the riskiness of different parts of the portfolio or how the portfolio can be diversified. As outlined above, to estimate the portfolio volatility we need to estimate the correlation between each pair of instruments. Unfortunately, this means that the number of parameters to be estimated grows quadratically with the number of instruments in the portfolio.[1] For most practical portfolios, the relatively large number of constituents makes it difficult to estimate the relationship between instrument returns in a robust way. Moreover, this framework uses the history of individual instrument returns to forecast future security return volatility. However,

1. As an example, if the portfolio has 10 instruments, we need to estimate 45 parameters, with 100 instruments we would need to estimate 4,950 parameters.

instrument characteristics are dynamic and hence using returns from different time periods may not produce good forecasts.[2] These drawbacks constitute the motivation for multifactor risk models discussed in this chapter.

One of the major characteristics of multifactor models is their ability to describe the return of a portfolio using a relatively small set of variables, called *factors*. These factors should be designed to capture broad (systematic) market fluctuations, but should also be able to capture specific nuances of individual portfolios. For instance, a broad fixed income market factor would capture the general movement in the fixed income markets, but not the varying behavior across types of instruments. If, for example, a portfolio is heavily biased toward the long end of the U.S. Treasury yield-curve, or is tilted toward credit bonds of particular industries, the broad market factor may not allow for a good representation of the portfolio's return. Other factors might be needed to capture these more specific sources of risk.

Most factor models are linear, in the sense that the total return is decomposed into the sum of the contributions of the factors (referred to as the *systematic return*) and an idiosyncratic component. *Systematic return* is the component of total return due to movements in the common (market-wide) risk factors. On the other hand, *idiosyncratic return* can be described as the residual component that cannot be explained by the systematic factors. Under most factor models, idiosyncratic returns are uncorrelated across issuers. Therefore, correlations across securities of different issuers are driven by their exposures to the systematic risk factors, and the correlation between those factors.

The following equation demonstrates the systematic and the idiosyncratic components of total return for security s:

$$r_s = L_s \times F + \varepsilon_s$$

The systematic return is the product of the instrument's loadings (L, also called sensitivities) to the systematic risk factors and the returns of these factors (F). The idiosyncratic return is given by ε_s.

Under these models, the portfolio volatility can be estimated as

$$\sigma_p^f = \sqrt{L_p^T \times \Sigma_F \times L_p + w^T \times \Omega \times w}$$

Here L_p are the loadings of the portfolio to the risk factors (determined as the weighted average of individual instrument loadings) and Σ_F is the covariance matrix of factor returns. Ω is the covariance matrix of the idiosyncratic security returns. Typically, the idiosyncratic return of securities is assumed uncorrelated. Therefore, this covariance matrix is diagonal, with all elements outside its diagonal being zero.[3] As a result, the idiosyncratic risk of the portfolio is diversified

2. This is especially the case over crisis periods, in which instrument characteristics can change dramatically over very short periods of time.
3. In more detailed factor models, idiosyncratic correlation may not be zero. For example, securities of the same issuer have typically positive correlation; in such case, the idiosyncratic covariance matrix is block-diagonal.

away as the number of securities in the portfolio increases. This is, of course, the diversification benefit attained when combining uncorrelated exposures.

For most practical portfolios, the number of factors is significantly smaller than the number of instruments in the portfolio. Therefore, the number of parameters in Σ_F is much smaller than in Σ_S, leading to a generally more robust estimation. Moreover, the factors can be designed in a way that they are relatively more stable than individual stock returns, leading to models with potentially better predictability. In this setting, the changing nature of each particular instrument can be captured through its loadings to the different risk factors.

Another very important advantage of using factor models is the detailed insight they can provide into the structure and properties of portfolios. These models characterize instrument returns in terms of systematic factors that (can) have intuitive economic interpretations. Linear factor models can provide important insights regarding the major systematic and idiosyncratic sources of risk and return. This analysis can help managers to better understand their portfolios and can guide them through the different tasks they perform, such as rebalancing, hedging, or tilting of their portfolios.

Naturally, the success of a risk model depends on its ability to interpret historical and current data in order to formulate estimates of future portfolio risk. It should therefore seek to discover properties of the data that are *quasi-predictable*; that is, that the error in the estimate of future realizations—given all information known today—is relatively small. For example, it is notoriously difficult to predict the expected return of a financial asset. On the other hand, historical data contain sufficient information to allow risk models to provide good estimates of the volatility of future returns. Nevertheless, one should never forget that even the most sophisticated risk model can only provide an *estimate* of risk. It is well known that financial markets are subject to *event risk* (i.e., a sudden change in market conditions cause by geopolitical or financial events). Such events are usually followed by a period of large negative returns of risky assets, large positive returns of assets considered as safe havens, significantly higher volatility, and very high (positive or negative) correlations. It is impossible for a risk model to predict when such events will occur. Therefore, it is useful to complement model-based risk management and portfolio construction with *what-if analysis,* which estimates portfolio return and risk under *stressed conditions*; that is, scenarios with extreme realizations of market returns and a covariance matrix with much higher volatilities and absolute correlations.

FIXED INCOME RISK MODELS

Fixed income securities are exposed to many different types of risk. Multifactor risk models in this area capture these risks by first identifying common sources along different dimensions, the *systematic fixed income risk factors*. All risk not captured by these systematic factors is considered *idiosyncratic*, and is determined by the choice of systematic risk factors. Typically, fixed income systematic risk

factors are divided into two sets: those that influence securities across asset classes (e.g., yield-curve risk) and those specific to a particular asset class (e.g., prepayment risk in securitized products).

There are many ways to define systematic risk factors. For instance, they can be defined purely by statistical methods, observed in the markets (e.g., a yield-curve), or estimated from asset returns. In fixed income, the standard approach is to use pricing models to calculate the analytics that are the natural candidates for risk factor loadings (L, in the notation presented earlier). In this setting, the risk factors are either observable (e.g., the movements in the yield-curve) or estimated from regressing cross-sectional asset returns on instrument sensitivities. This is the approach taken in the Barclays Capital Global Risk Model,[4] which is the model used for illustration throughout this chapter.

In this risk model, the forecasted risk of the portfolio is driven by both a systematic and an idiosyncratic (also called specific, nonsystematic, or concentration) component. The forecasted systematic risk is a function of the mismatch between the portfolio and the benchmark in the exposures to the risk factors, such as yield-curve or spreads. The (net) portfolio exposures are aggregated from security-level analytics. The systematic risk is also a function of the volatility of the risk factors, as well as the correlations between the risk factors. In this setting, the correlation of returns across securities is driven by the correlation of systematic risk factors these securities load on. Because the model uses security-level returns and analytics to estimate the factors, it can recover the idiosyncratic return for each security. This is the return net of all systematic factors. The use of detailed level analysis of idiosyncratic returns allows for the estimation of rich specifications of idiosyncratic risk.

Systematic Risk Factors

The precise definition of systematic risk factors depends on the purpose of the factor model, but in general we can highlight several categories of risk factors that drive fixed income risk.

Curve Risk

Curve risk is the major source of risk across fixed income instruments. This kind of risk is embedded in virtually all fixed income securities; therefore, mismatches in curve profiles relative to a benchmark are often the main drivers of portfolio risk.

4. The Barclays Capital Global Risk Model is available through POINT, Barclays Capital portfolio management tool. It is a multi-currency cross-asset model that covers many different asset classes across the fixed income and equity markets, including derivatives in these markets. At the heart of the model is a covariance matrix of risk factors. The model has several hundreds of factors, many specific to a particular asset class. The asset class models are periodically reviewed. Structure is imposed to increase the robustness of the estimation of such large covariance matrix. The model is estimated from historical data. It is calibrated using extensive security-level historical data and is updated on a monthly basis.

When analyzing curve risk, we should use the curve of reference in which we are interested. Depending on the portfolio and circumstances, this is typically the government or swap curve.[5] In calm periods, the behavior of the swap curve tends to match that of the government curve. However, during liquidity crises (e.g., the Russian crisis in 1998 or the credit crisis in 2008), they can diverge significantly. To capture these different behaviors adequately, one may use the following decomposition: for government products, the curve risk is assessed using the government curve. For all other products in the portfolio (that usually trade off the swap curve), this risk is measured using both the Treasury curve and swap spreads (i.e., the spreads between the swap and the government curve). Other curve decompositions are also possible.

The risk associated with each of these curves can be described by the exposure the portfolio has to different points along the curve combined with the volatility and correlation of the movement of such curve points. Sometimes a convexity term is required to capture the second-order exposure to curve changes of instruments with long tenors or embedded optionality, such as mortgage-backed securities. For a typical portfolio, a good description of the curve can be achieved by looking at a relatively small number of points along the curve (called key-rates), for example 6-month, 2-year, 5-year, 10-year, 20-year, and 30-year. An alternative set of factors used to capture yield-curve risk can be defined using statistical analysis of the historical realizations of the various yield-curve points. The statistical method used most often is *principal component analysis* (PCA). This method defines factors that are statistically independent of each other. Typically three or four such factors are sufficient to explain the risk associated with changes of yields across the yield-curve. PCA analysis has several shortcomings and must be used with caution. Using a larger set of economic factors like the key-rate points described above is more intuitive and captures the risk of specialized portfolios better. For these reasons, many portfolio managers favor the key-rates approach in most risk analysis problems.

Credit Risk

Instruments issued by corporations or entities that may default are said to have credit risk. The holders of these securities demand additional yield—in excess of the risk-free yield—to compensate for that risk. This extra yield is usually measured as a spread to a reference curve. For instance, for corporate bonds the reference curve is usually the swap curve. The level of credit-spreads determines to a large extent the credit risk exposure associated with the portfolio.[6]

There are several characteristics of credit bonds that are naturally associated with systematic sources of credit-spread risk. For instance, depending on the

5. Other curves that can be used are, for instance, the municipals (tax-free) curve, the inflation-adjusted (real rate) curve, etc.

6. Spreads are also compensation for sources of risk other than credit (e.g., liquidity), but for the sake of our argument, we treat them here as major indicators of credit risk.

business cycle, particular industries may be going through especially tough times. So industry membership is a natural systematic source of risk. Similarly, bonds with different credit ratings are usually treated as having different levels of credit risk. Credit rating could be another dimension one can use to measure systematic exposure to credit risk. Finally, the country of the issuer is another source of systematic risk for credit bonds. Given these observations, it is common to see factor models for credit risk using country, industry, and rating as the major systematic risk factors. Recent research suggests that risk models that directly use the spreads of the bonds instead of their ratings perform better for risk analysis over relatively short/medium horizons.[7] Under this approach, the loading of a particular bond to a credit-risk factor would be the commonly used spread duration, but now multiplied by the bond's spread. The loading is termed *D*uration *T*imes *S*pread (denoted DTS) and is described in Chapter 55. By directly using the spread of the bond in the definition of the loading to the credit risk factors, we do not need to assign specific risk factors to capture the rating or any similar quality-like effect. It will be automatically captured by the spread level incorporated into the bond's loading to the credit risk factor, and will adjust as the spread of the bond changes. In this setting, we still could use different systematic risk factors, for example, to distinguish among credit risk coming from different industries.[8]

Prepayment Risk

Securitized products are generally exposed to prepayment risk. The most common of the securitized products are the residential mortgage-backed securities (RMBS or simply MBS). These securities represent pools of deals that allow the borrower to prepay their debt before the maturity of the loan/deal, most typically when prevailing lending rates are lower. This option means an extra risk to the holder of the security, the risk of holding cash exactly when reinvestment rates are low. Therefore, these securities have two major sources of risk: interest rate (including convexity) and prepayment risk.

---

7. For details, see Arik Ben Dor, Lev Dynkin, Patrick Houweling, Jay Hyman, Erik van Leeuwen, and Olaf Penninga, "A New Measure of Spread Exposure in Credit Portfolios," Barclays Capital Publications, February 2010.
8. The general principle of a risk model is that the historical returns of assets contain information that can be used to estimate the future volatility of portfolio returns. However, good risk models must have the ability to translate the historical asset returns to the context of the current environment. This translation is made when designing a particular risk model/factor and when implemented delivers risk factors that are as invariant as possible. This invariance makes the estimation of the factor distribution much more robust. In the particular case of the DTS, by including the spread in the loading (instead of using only the typical duration), we change the nature of the risk factor being estimated. The factor now represents percentage change in spreads, instead of absolute changes in spreads. The former has a significantly more invariant distribution. For more details, see Antonio B. Silva, "A Note on the New Approach to Credit in the Barclays Capital Global Risk Model," Barclays Capital Publications, September 2009.

Some part of the prepayment risk can be expressed as a function of interest rates via a prepayment model. This risk will be captured as part of interest-rate risk using the key-rate durations and the convexity. Convexity, which is usually negative for these instruments, is a significant source of risk. Negative convexity has a detrimental effect on the market value of an instrument—compared with one with positive or zero convexity—when interest rates move significantly in either direction. Indeed, decreasing interest rates cause prepayments to increase thereby reducing the price appreciation because of the falling rates. Conversely, rising interest rates intensify the price depreciation the instrument suffers with higher rates.

The remaining part of prepayment risk—that is not captured by the prepayment model—must be modeled with additional systematic risk factors. Typically, the volatility of prepayment speeds (and therefore of risk) on MBS depends on three characteristics: program/term of the deal, if the bond is priced at discount or premium (e.g., if the coupon on the bond is bigger than the current mortgage rates), and how seasoned the bond is. This analysis suggests that the systematic risk factors in a risk model should span these three characteristics of the securities.

Implied Volatility Risk

Many fixed income securities have embedded options (e.g., callable bonds). This means that the expected future volatility (implied volatility[9]) of the interest rate or other discount curves used to price the security plays a role in the value of that option. If expected volatility increases, options generally become more expensive, thereby affecting the prices of bonds with embedded options. For example, callable bonds will become cheaper with increasing implied volatility since the bondholder is short optionality (the right of the issuer to call the bond). Therefore, the exposure of the portfolio to the implied volatility of the yield-curve is also a source of risk that should be accounted for. The sensitivity of securities to changes of implied volatilities is typically measured by *vega*, which is calculated using the security pricing model. Implied volatility factors can be either calculated from the market prices of liquid fixed income options (caps, floors, and swaptions), or implied by the returns of bonds with embedded options within each asset class.

Liquidity Risk

Many fixed income securities are traded over-the-counter, in decentralized markets. Some trade infrequently, making them illiquid. It is therefore hard to establish their fair price. These bonds are said to be exposed to liquidity risk. The holder of illiquid bonds would have to pay a higher price to liquidate a position, usually meaning selling at a discount. This discount is uncertain and varies across the business cycle. For instance, the discount can be significant in a liquidity

9. The volatility is called implied because it is calculated from the market prices of liquid options with the help of an option-pricing model.

crisis, such as the one of 2008. The uncertainty about this discount means that, everything equal, a more illiquid bond will be riskier. This extra risk can be captured through liquidity risk factors. For instance, in the Treasury markets, one generally refers to the difference in volatility between an on-the-run and an off-the-run Treasury bond as liquidity risk.

Inflation Risk

Inflation-linked securities are priced based on the expectation of future inflation. Uncertainty about this variable adds to the volatility of the bond over and above the volatility from other sources of risk, such as nominal interest rates. Expected inflation is not an observed variable in the marketplace but can be extracted from the prices of inflation-linked government bonds and inflation swaps. Expected inflation risk factors can be constructed by summarizing this information. The sensitivity of securities to expected inflation is calculated using a specialized pricing model and is usually called *inflation duration*.

Tax-Policy Risk

Many municipal securities are currently tax-exempt. This results in added benefit to their holders. This benefit—incorporated in the price of the security—depends on the level of exemption allowed. Uncertainty around tax policy—tax-policy risk—adds to the risk of these securities. Once again, tax-policy risk factors cannot be observed in the marketplace and must be extracted from the prices of municipal securities. The return of municipal securities in excess of interest rates is driven partially by tax-policy expectations changes. However, it is also driven by changes in the creditworthiness of the municipal issuers as well as other factors. In this case, it is difficult to separate tax-policy risk factors from other factors driving municipal bond spreads. Therefore, instead of specific tax-policy factors, we usually extract factors representing the overall spread risk of municipal securities. This exercise is performed in a similar way to the credit risk model, in which securities are partitioned into groups of "similar" risk by geography, bond type (general obligation vs. revenue), tax status, and the like.[10]

There are other sources of systematic risk we did not detail in this section. They may be important sources of risk for particular portfolios. Specific risk models and factors can be designed to address them.

Idiosyncratic Risk

Once all systematic factors and loadings are determined, the residual idiosyncratic return of a security can be computed as the component of its total return that cannot be explained by the systematic factors. Idiosyncratic return can be a significant component of total return for individual instruments, but tends to decrease rapidly

10. For more discussion, see Arne Staal, "U.S. Municipal Bond Risk Model," Barclays Capital Publications, July 2009.

for portfolios of instruments as the number of instruments increases and concentration decreases (the aforementioned diversification effect).

The major inputs to the computation of idiosyncratic risk are instrument characteristics and historical idiosyncratic returns of the instruments. The use of idiosyncratic residual returns allows the risk modeler to find empirical relationships between characteristics such as instrument spread, spread duration, industry membership, and idiosyncratic volatility. This mapping of instrument characteristics to idiosyncratic volatility allows for the modeling of new issues and issues with characteristics that change over time. As mentioned before, idiosyncratic returns of different issuers are assumed to be uncorrelated. However different securities from the same issuer, or securitized products with related underlying instruments, can show a certain level of co-movement, as they are all exposed to specific events affecting their common issuer that are not captured by systematic risk factors. Interestingly, this co-movement is not perfect or static. Certain news can potentially affect the different securities issued by the same company (e.g., equity, credit default swaps, bonds, or equity options) in different ways. Moreover, this relationship changes with the particular circumstances of the firm. For instance, returns from securities with claims to assets of the firm should be more highly correlated if the firm is in distress. A good multi-asset class risk model should be able to capture these phenomena regarding idiosyncratic risk.

APPLICATIONS OF RISK MODELING

In this section, we illustrate several standard risk model applications used for portfolio management. All applications make use of the fact that the risk model translates the characteristics a portfolio may have across many different dimensions, into a common, comparable set of numbers. In some of them—risk budgeting and portfolio rebalancing—an optimizer that uses the risk model as an input is the optimal setting to perform the exercise.

The investment process of a typical portfolio manager involves different stages. Given the investment universe and objective, the steps usually consist of portfolio construction, risk prediction, and performance evaluation. These steps are iterated throughout the investment cycle over each rebalancing period. The examples in this section highlight the portfolio construction and risk analysis steps that employ a factor model. Additionally, scenario analysis can be employed in both the portfolio construction and risk evaluation phases of the portfolio process. This exercise allows the manager to gain additional intuition regarding portfolio exposures and how the portfolio may behave under particular economic circumstances. It usually takes the form of stress testing potential portfolio losses under historical or hypothetical scenarios. It can also show the sensitivity of the portfolio to particular movements in economic and financial variables. The last application in this chapter illustrates this kind of analysis.

Portfolio Construction and Risk Budgeting

As discussed, fixed income portfolios are exposed to a diverse set of risk factors. During the portfolio construction exercise, the manager must carefully choose the exposure to such factors in order to achieve the highest possible portfolio return subject to risk and other constraints. Risk models help portfolio managers achieve this in an objective and quantifiable way and are increasingly used for portfolio construction, usually with the help of an optimization engine. In this section, we illustrate how a portfolio manager would use this engine to formulate client objectives and constraints in the context of risk model-based portfolio construction.[11]

Portfolio managers can have a broad array of mandates. Some—typically referred to as *indexers*—are required to follow a given benchmark index with the minimum possible deviation. Their goal is to minimize the tracking error volatility of the portfolio versus the index while also keeping portfolio transaction costs as small as possible. Others, the *enhanced indexers*, are allowed some leeway to deviate from the benchmark in order to achieve superior returns. The leeway can be expressed as a set of rules constraining the exposure to risk factors, but it is often prescribed as a *risk budget*; that is, an upper limit in a statistical measure of deviation between the portfolio and its benchmark. The *tracking error volatility* (TEV) of the return of the portfolio net of the benchmark is the most common of such measures. Finally, the *absolute return* portfolio managers, do not have to track a benchmark but are instead aiming at the highest possible portfolio return, potentially subject to leverage, portfolio composition, exposure, and risk constraints. In all cases, the manager has to merge all views and constraints into a final portfolio. When constructing the portfolio, how can the competing views be managed, while respecting the risk budget? How can the views be combined to minimize the risk? What tradeoffs can be made? Risk models are widely used to perform this exercise in a systematic and objective manner: They can measure the risk of each view as well as the correlation between different views, and arrive at portfolios that optimally trade-off the risks and expected returns associated with each of the views.

We illustrate this by a simple example of a portfolio construction exercise using a risk model. Consider a fixed income portfolio manager who is benchmarked to the Barclays Capital U.S. Aggregate index. The manager's mandate is to outperform the benchmark with a risk-budget of 20 bp/month (i.e., the portfolio's TEV should remain within this bound on a monthly basis). Before formulating views and constraints, and deciding how to implement them, the manager needs to choose an investment universe. Since the benchmark is the Barclays Capital U.S. Aggregate Index, the manager could choose the investment universe to be all issues in this index with outstanding amount in excess of $300 million. The selection of this investment universe ensures that securities with small amounts of outstanding notional will not be selected in the portfolio, potentially increasing overall portfolio liquidity and decreasing transaction costs. With the

11. In our examples, we use the Barclays Capital POINT optimization engine.

risk budget in mind, the manager chooses to minimize total portfolio TEV relative to the benchmark. (The manager could potentially consider other risk-based objectives such as maximizing the Sharpe ratio.) This means the manager is giving leeway to the risk model to choose a portfolio from the tradable universe that minimizes the risk relative to the benchmark, in this case the Barclays Capital U.S. Aggregate Index. Finally, the manager formulates constraints and views.

Let us assume for the purpose of this illustration that the amount of funds to be invested is $100 million. With that in mind, and in order to avoid buying small amounts of securities, the manager decides to implement the portfolio using a maximum of 100 positions. Given views on the market environment, the manager wants the portfolio to be long duration against the benchmark, between 0.40 and 0.60 years, and have a spread advantage of 150 bp to 200 bp over the benchmark. Finally, to ensure a certain amount of diversification in portfolio positions, the manager imposes a maximum under/overweight of 3% per issuer relative to the benchmark.[12]

Our portfolio manager incorporates all these settings into an optimization problem, and finds a solution that reflects the optimal tradeoff between the constraints and risks through the optimization engine. The result is a recommended portfolio that satisfies the constraints while minimizing total risk. Specifically, the resulting portfolio—that we will follow throughout this section—consists of 100 securities, has a predicted TEV of 15.1 bp/month, interest-rate duration of 5.44 years, and option-adjusted spread of 206 bp (Exhibit 46–1). Using a factor-based risk model and an optimization engine, the resulting portfolio incorporates the manager's views while staying within its risk budget and ensuring that all additional constraints are satisfied.

Analyzing Portfolio Risk

The main application of risk models is risk measurement of portfolios relative to their benchmark. Risk analysis based on multifactor models can take many forms: from a relatively high-level aggregate approach, to an in-depth analysis of the risk

EXHIBIT 46–1

Portfolio and Benchmark Characteristics of Sample Portfolio

	Total TEV (bp/month)	Duration (years)	Spread Duration (years)	Spread (bp)
Portfolio	15.1	5.44	5.23	206
Benchmark		5.02	4.92	55

Source: Barclays Capital POINT.

12. Another way to ensure diversification would be to include the minimization of the idiosyncratic TEV as a specific goal in the objective function.

properties of individual instruments and groups of instruments. Multifactor fixed income risk models provide the tools to perform the analysis of portfolio risk in many different dimensions, including exposures to risk factors, security/factor contributions to total risk, and risk analysis at the issuer level. For instance, as previously described, this risk can be decomposed into a systematic and an idiosyncratic component. Exhibit 46–2 shows that the portfolio has total TEV of 15.1 bp/month, systematic TEV of 10.4 bp/month, and idiosyncratic TEV of 10.1 bp/month. Since systematic risk and idiosyncratic risk are independent, they constitute isolated (uncorrelated) risk sources of the portfolio and therefore we have

$$\text{Total TEV} = \sqrt{\text{Systematic TEV}^2 + \text{Idiosyncratic TEV}^2}$$

An alternative way to describe the manner in which different risk sources impact overall portfolio risk is through *risk attribution*. Risk attribution allows a manager to decompose portfolio volatility in an additive way into contributions to TEV. Exhibit 46–2 reports that the contribution to total TEV (CTEV) from systematic risk factors is 8.3 bp/month, whereas idiosyncratic risk contributes 6.8 bp/month.[13]

The risk attribution approach can be used to further decompose overall portfolio risk into contributions from different buckets. The buckets can represent groups of securities (e.g., industry buckets) or risk factors (e.g., factors related to curve or to credit-spreads). This flexible decomposition allows portfolio managers to gain a detailed understanding of how different securities and risk exposures affect overall portfolio risk.

Exhibit 46–3 shows the isolated TEV as well as the contributions to TEV for the sample portfolio. In this exhibit, we choose to partition risk across systematic risk factors (plus the idiosyncratic risk), but many other partitions are possible. In this example, the largest contribution within systematic risk comes

EXHIBIT 46–2

Portfolio Risk Results of Sample Portfolio in bp/Month

	Isolated TEV	CTEV
Total	15.1	15.1
Systematic	11.2	8.3
Idiosyncratic	10.1	6.8

Source: Barclays Capital POINT.

13. In this case, because the systematic and idiosyncratic components of the TEV are uncorrelated, the CTEV can be computed easily. Specifically, the CTEV from the systematic risk is computed as $11.2^2/15.1 = 8.3$ and from the idiosyncratic as $10.1^2/15.1 = 6.8$. Note that by definition they sum up to the total TEV. In Chapter 47 a more detailed and general discussion is provided.

EXHIBIT 46–3

Portfolio Risk Contributions of Sample Portfolio in bp/Month

Risk Factor Partition Bucket	Isolated TEV	CTEV
Total	15.1	15.1
Systematic	11.2	8.3
Curve	11.4	5.2
Swap Spreads	2.6	0.6
Volatility	0.4	0.0
Spread Gov-Related	3.4	0.0
Spread Credit and EMG	7.5	2.6
Spread Securitized	3.0	–0.1
Idiosyncratic	10.1	6.8

Source: Barclays Capital POINT.

from the exposure to "Curve" factors, with a CTEV of 5.2 bp/month. As we saw before, idiosyncratic exposure is also a large component of the risk in this portfolio, with a contribution of 6.8 bp/month to total risk. Notice the difference between isolated TEV and contribution to TEV for our factor partition—isolated TEV reflects the risk of the partition buckets in isolation—while contribution to TEV includes risk driven by correlations among the different buckets.

In addition to overall portfolio TEV and partition-based contributions to TEV, there are many additional risk analytics that can be computed on the basis of a linear factor risk model, such as betas with respect to the benchmark, liquidation effect to TEV, and marginal contributions to risk. Different users will use these analytics for different purposes and to different degrees.

Portfolio Rebalancing

Most managers rebalance their portfolios at regular intervals to reflect changing views and market circumstances. For instance, as time goes by, the characteristics of the portfolio may drift away from targeted levels. This may be due to the aging of its holdings, changes in the market environment, or issuer-specific events such as defaults. The periodic realignment of a portfolio to its investment guidelines and changing investment views is called *portfolio rebalancing*. Similar needs arise in many different contexts: when managers receive extra cash to invest, receive minor changes to their mandate, want to tilt positions toward their views, and the like. As with the initial portfolio construction, a risk model is very useful in the rebalancing exercise. During rebalancing, typically the portfolio manager

seeks to sell bonds currently held and replace them with others having properties more consistent with the overall portfolio goals. Such buy and sell transactions are costly and their cost must be weighed against the benefit from moving the portfolio closer to its desired profile. A risk model can tell the manager how much risk reduction (or increase) a particular set of transactions can achieve in order to evaluate the risk adjustment benefits relative to the transaction cost.

As an example, suppose the portfolio manager in our illustration wants to reduce the imbalances the portfolio has against the benchmark. Specifically, the manager wants to lower the net portfolio duration from 0.42 years to a value between 0.2 years and 0.4 years. After looking at the portfolio's industry profile, the manager also decides to reduce the existing 6% overweight in the banking industry to about 4%. In addition, the manager lowers the minimum acceptable excess spread to 100 bp. To avoid high transaction costs, the manager also imposes the rebalancing to be done with no more than 30 trades. Finally, let us assume no portfolio inflows or outflows so the portfolio market value must remain unchanged. Starting from the original portfolio of 100 securities, a risk model and optimization engine can be employed to achieve optimal rebalancing by adjusting some of the constraints to reflect the portfolio manager's new objectives.

Exhibit 46–4 shows the largest trades suggested by the optimizer, in terms of market value. Not surprisingly, the largest sell recommendations are of financial companies. To replace them, the optimizer—using the risk model—recommends

a larger position of Treasury and corporate bonds. (Corporates are required in order to keep the spread of the portfolio at the desired level.)

Interestingly, the rebalancing and extra constraints imposed on the optimization problem did not materially change the risk of the portfolio. Exhibit 46–5 shows that the total TEV of the portfolio actually decreased to 13.4 bp/month. This is largely due to an extra 13 positions added to the portfolio in the rebalancing (that now has 113 securities). These extra securities allowed the portfolio to reduce both its systematic and idiosyncratic risk.

Scenario Analysis

Scenario analysis is a popular tool both for risk management and portfolio construction. In this section, we illustrate a way to construct scenarios based on factor models. In this context, a portfolio manager express views on the returns of particular financial variables, indices, securities or risk factors and the scenario analysis tool (using the risk model) calculates their impact on the portfolio's (net) return.

Typically in this kind of scenario analysis, the views one has are only partial. This means one can have specific views on how particular macro variables, asset classes, or risk factors will behave, but it is unlikely to have views on all risk factors to which the portfolio under analysis is exposed. This is where risk models can be useful. At the heart of the linear factor models lies a set of risk factors and the covariance matrix between them. Under certain statistical assumptions, the covariance matrix can be used to "complete" specific partial views or scenarios and deliver a complete picture of the impact of the scenario in the return of the portfolio. Mechanically, what happens is the following. First, the manager translates the views into realizations of a subset of risk factors. Next the scenario is completed—using the risk model covariance matrix—to get the realizations of *all* risk factors. Finally, the portfolio's (net) loadings to all risk factors are used to get its (net) return under that scenario (by multiplying the loadings by the factor realizations under the scenario). This construction implies a set of assumptions that should be carefully understood. To begin with, it is assumed that the manager can represent or translate views as risk factor returns. So a view about the unemployment rate,

EXHIBIT 46–5

Rebalanced Portfolio and Benchmark Characteristics

	Total TEV (bp/month)	Duration (years)	Spread Duration (years)	Spread (bp)
Portfolio	13.4	5.31	5.06	153
Benchmark		5.02	4.92	55

Source: Barclays Capital POINT.

which is typically not used as a risk factor,[14] cannot be used in this context. Also, to "complete" the scenario, we generally assume a stationary and normal multivariate distribution among all factors. Although these assumptions make this analysis less appropriate for looking at extreme events or regime shifts, for instance, the analysis can be very useful in many circumstances.

As an example, consider using factor-based scenario analysis to compute the model-implied empirical durations of the original portfolio of a 100 securities (i.e., before rebalancing) analyzed in detail previously in this chapter. In particular, suppose the portfolio manager has the view that interest rates will fall by 25 bp over the next month. Exhibit 46–6 shows that under this scenario, the portfolio returns 116 bp, against the 111 bp of the benchmark. As expected given the longer duration, the portfolio outperforms the benchmark. Due to the other exposures present in the portfolio and benchmark and their average negative correlation with the curve factors—for instance, a 25 bp fall in rates under this setting implies a 5% increase in corporate spread levels—the model duration implied by the scenario for the portfolio is 4.64 (= 116/25), while the analytical duration is 5.44. The scenario shows a similar decrease in the benchmark's duration. The net model duration of the portfolio is only 0.22, almost half of its 0.42 net analytical duration.

Another characteristic imposed while constructing the portfolio was a targeted higher spread. The portfolio construction exercise resulted in an OAS for the portfolio of 206 bp against a spread level of 55 bp for the benchmark. The portfolio manager might be concerned with portfolio losses should spreads increase. To evaluate this risk, the portfolio manager can construct two scenarios. In the first scenario, credit-spreads widen by 20%, other spread risk factors move as implied by the credit-spread moves, but interest rates remain unchanged. In the second scenario, interest rates moves are implied by the credit-spread move. Exhibit 46–7 displays the results of the two scenarios. In the first scenario, the portfolio suffered significant losses of 0.84%. The benchmark which has a much lower spread suffers lower losses of 0.64% and the net result is –20

bp of net return. This number is very different from a back of the envelope calculation that uses portfolio-level analytics to estimate the return. The calculation is much more intricate and takes into account the security level portfolio composition, as well as the implied moves of other sources of risk such as swap and mortgage spreads.

Things look better in the second scenario, where the net return of the portfolio versus the benchmark is only –9 bp. In fact, in this case both the portfolio and the benchmark exhibit positive returns of 0.49% and 0.58%, respectively, illustrating that this is a very different type of scenario. Indeed, the large spread widening implies a 25 bp fall in interest rates, which is sufficient to overcome the losses from the spread widening for both the portfolio and the benchmark. Since the portfolio has interest rate duration that is 0.42 years longer than the benchmark, it enjoys a relative improvement in net return of about -0.42×-25 bp = +10.5 bp that partially offsets the losses from the widening of credit spreads.

These very simple examples illustrate how one can look at reasonable scenarios to study the behavior of the portfolio or the benchmark under different environments. This type of factor-based scenario analysis can significantly increase the intuition the portfolio manager has regarding the results from the risk model.

KEY POINTS

- Risk models describe the different imbalances of a portfolio using a common language. The imbalances are combined into a consistent and coherent analysis reported by the risk model.
- Risk models provide important insights regarding the different tradeoffs existing in the portfolio. They provide guidance regarding how to balance them.

- The fundamental systematic risk of all fixed income securities is interest rate and term structure risk. This is captured by factors representing risk-free rates and swap spreads of various maturities.
- Excess (of interest rates) systematic risk is captured by factors specific to each asset class. The most important components of such risk are credit risk and prepayment risk. Other risks that can be important are volatility, liquidity, inflation, and tax policy.
- Idiosyncratic risk is diversified away in large portfolios and indices, but can become a very significant component of the total risk in small portfolios. The correlation of idiosyncratic risk of securities of the same issuer must be modeled very carefully.
- A good risk model provides detailed information about the exposures of a complex portfolio and can be a valuable tool for portfolio construction and management. It can help managers construct portfolios tracking a particular benchmark, express views subject to a given risk budget, and rebalance a portfolio while avoiding excessive transaction cost. Further, by identifying the exposures in which the portfolio has the highest risk sensitivity, it can help a portfolio manager reduce (or increase) risk in the most effective way.

Portfolio managers constantly monitor their exposures, typically net of a benchmark, and routinely ask themselves: What is the portfolio interest-rate duration? How risky is the overexposure to Treasuries? How does it relate to the exposure to credit? What is the exposure to specific issuers? Knowing portfolio holdings and exposures are not enough for portfolio managers, they increasingly rely on quantitative techniques to translate this information into a standard risk language, which allows comparisons across diverse portfolios or situations. Risk models present a consistent view of the portfolio, its exposures, and how they relate to each other. They quantify the risk of each exposure and its contribution to the overall risk of the portfolio.

Chapter 46 covered linear factor models for fixed income portfolios. In this chapter we detail an application of the models for risk forecasting that can be used to monitor risk and gain insightful information regarding the exposures of a portfolio.

The authors would like to thank Bruce Phelps and Andy Sparks for their valuable comments.

APPROACHES USED TO ANALYZE RISK

Throughout this chapter we analyze the risk of a particular bond portfolio, going through the various aspects of risk typically looked at by a manager. We follow a portfolio manager. We assume the following:

- The Barclays Capital U.S. Aggregate Index is the portfolio manager's benchmark.
- The portfolio manager believes interest rates are coming down. To capitalize on this view, the manager seeks to create a portfolio with interest-rate duration longer than the interest-rate duration of the benchmark. A portfolio with interest-rate duration that exceeds that of the benchmark is referred to as being "long duration" and it outperforms the benchmark when interest rates fall and all other market factors remain unchanged.
- The manager seeks a portfolio with higher yield than the one of the benchmark. Such a portfolio creates superior carry return (also known as *income*) relative to the benchmark but is subject to increased risks. The total yield of a portfolio can be decomposed into a risk-free yield and a spread over the risk-free yield. Because the portfolio is expected to contain securities with longer maturities to satisfy the long duration target, it will earn a risk-free yield that is different from the risk-free yield of the benchmark (higher most of the time since typically interest-rate curves are upward sloping).To further enhance the portfolio yield, the manager wants to target a portfolio spread that is also higher than the spread of the benchmark. Higher spread typically exposes the portfolio to liquidity and issuer default risks. If defaults occur, or if the portfolio manager is forced to sell securities at a significant discount because of lack of liquidity, then the incurred losses may cancel out the higher yield advantage and could lead to portfolio underperformance relative to the benchmark. The manager must be comfortable that such risks are sufficiently compensated by the higher carry return associated with higher portfolio spread.
- The portfolio manager is required to maintain the difference between the returns of the portfolio and the benchmark at around 20 basis points, on a monthly basis. Therefore, the portfolio manager must calibrate the long duration and high-yield portfolio positions in order to abide by this constraint.

To summarize, the portfolio manager has the mandate to track the benchmark, but is allowed to deviate from it up to a point in order to express views that may lead to superior returns. As mentioned in Chapter 46, a portfolio manager with such a mandate is called an *enhanced indexer*. The amount of deviation allowed is called the *risk budget* (20 basis points in our example) and can be quantified using a risk

model. The risk model produces an estimate of the volatility of the difference between the portfolio and the benchmark returns, called *tracking error volatility* (TEV).[1] TEV gives the forecasted magnitude of the typical tracking error. The manager should keep the portfolio's TEV at a level equal to or less than that specified in risk budget. The final portfolio, which we will analyze, contains 100 securities and is consistent with the manager's views and risk budget.

Market Structure and Exposure Contributions

The portfolio manager starts the analysis by comparing the portfolio holdings with the holdings of the benchmark. Exhibit 47–1 shows that the portfolio composition has several important mismatches relative to the benchmark. The portfolio is underweighted in Treasuries and government-related securities by a combined 9.0%. This is compensated with a combined overweight of 11.2% in Corporates, especially in the Industrials and Financials sectors. These sectors have almost double the weight in the portfolio versus the benchmark. Other mismatches include an underweight in agency mortgage-backed securities (agency MBS) by

EXHIBIT 47–1

Market Weights for Portfolio and Benchmark

Asset Class	Portfolio	Benchmark	Difference
Total	**100.0**	**100.0**	**0.0**
Treasury & Govt-Related	**36.8**	**45.8**	**–9.0**
Treasury	30.8	33.8	–3.0
Government-Related	6.0	12.0	–6.0
Corporates	**29.9**	**18.7**	**11.2**

1. In this chapter we refer to TEV, risk, and "the standard deviation of the portfolio net returns" interchangeably.

3.8% and an overweight in commercial mortgage-backed securities (CMBS) by 1.9%. Notice that the quest for yield pushed the manager out of the relatively safe (in terms of default risk) Treasury and agency MBS sectors and into more risky corporate and CMBS sectors.

If the manager were focusing on equities instead of fixed income, this kind of information—for example, applied to the different industries or sectors of the portfolio—would be of paramount importance for portfolio risk analysis. For a fixed income portfolio, this is not the case. Although important, this analysis tells us little about the true active exposures of a fixed income portfolio, owing to the diverse nature of fixed income securities. What if the Treasuries in the portfolio have significantly longer duration than those in the benchmark— would we be really "short" in this asset class? What if the spreads from CMBS in the portfolio are much smaller than those in the benchmark—is the weight mismatch that important?

To answer these kinds of questions, we turn to another typical dimension of analysis: the portfolio exposure to major sources of risk, measured with analytics such as interest-rate duration. Exposures to other sources of risk typically monitored include spread duration, convexity, spread level, and Vega (if the portfolio has many securities with optionality, such as mortgages or callable bonds). Their associated risks have been discussed in Chapter 46.

In Exhibit 47–2 we present these analytics at the aggregate level for the portfolio, benchmark, and the difference between the two. We can see that

- The portfolio is long interest-rate duration (0.38 years), reflecting the forecast the manager has regarding the direction of interest rate moves.
- In terms of spread duration, the mismatch is smaller (0.29 years). The manager wants to minimize the exposure to spread changes as much as possible given the manager has no view on this source of risk. However,

EXHIBIT 47–2

Aggregate Analytics

Analytics	Portfolio	Benchmark	Difference
Interest-Rate Duration	5.36	4.98	0.38
Spread Duration	5.20	4.91	0.29
Convexity	0.14	–0.04	0.18
Vega	–0.03	–0.02	–0.01
Spread	204	56	148

Source: Barclays Capital POINT

the spread duration mismatch cannot be zero because spread risk is related to other risks that she does have a view on, such as rates.

- The portfolio and the benchmark have convexity with opposite signs (0.14 for the portfolio versus –0.04 for the benchmark). This is attributable to the smaller weight MBS have in the portfolio.
- The portfolio also has a higher negative Vega, but the number is reasonably small for both universes.
- The portfolio has significantly higher spread (148 bp) than the benchmark. This mismatch is consistent with the manager's goal of having a higher yield in her portfolio than the benchmark.

We can combine the analysis in Exhibits 47–1 and 47–2 to create a more detailed picture of where the different risk exposures are coming from. Exhibit 47–3 shows one such example for the portfolio interest-rate duration. The majority of the mismatch in interest-rate duration contribution (market weighted duration exposures) comes from the Treasury component of the portfolio (0.60 years). Interestingly, even though the portfolio is short in Treasuries, it is actually long in terms of interest-rate duration for that asset class. This means that a Treasury sell-off, meaning an increase in rates, would impact the portfolio more negatively than the benchmark. Because the portfolio is net short Treasuries, this result must mean that the Treasury portfolio is longer in interest-rate duration than the benchmark's Treasury component. Conversely, Corporates have negative contribution to net interest-rate duration, even though they are over-weighted in terms of market value. This means that on average the corporate bonds in the portfolio are significantly shorter in interest-rate duration than those in the benchmark. Note that this kind of analysis could be applied to other analytics of interest, such as to spread or spread duration.

EXHIBIT 47–3

Duration Contribution per Asset Class

Interest-Rate Duration Contribution	Portfolio	Benchmark	Difference
Total	**5.36**	**4.98**	**0.38**
Treasury	2.38	1.78	0.60

Adding Volatility and Correlations into the Analysis

The analysis above gives the manager some basic understanding of the portfolio exposures to different kinds of risk. However, it is still hard to understand how the portfolio manager can compare the level of risk across these different exposures. What is more risky, the long interest-rate duration exposure of 0.38 years, or the extra spread of 148 bp? How can the portfolio manager quantify how serious is the portfolio's Vega mismatch? Specifically, the risk of the portfolio is a function of the exposures to the risk factors, but also of how "risky" each of the factors is.

To enhance the analysis we must bring factor volatilities into the picture. Exhibit 47–4 shows the outcome of this addition to our example. In particular, it displays the risk of the different exposures of the portfolio in isolation (that is, if the only active imbalances were those from that particular set of risk factors). For example, this exhibit shows that if the only active weight in the portfolio were the mismatch in the yield-curve exposures, the risk of the portfolio would be 11.3 bp/month. By adding volatilities into the analysis, the manager can now quantify that the mismatch of 0.38 years in interest-rate duration "costs" the portfolio 11.3 bp/month of extra volatility, when taken in isolation, and therefore refer to this as the Isolated TEV.[2] Remember that the portfolio's total risk budget is 20 bp/month. Similarly, if the only mismatch were the exposure to corporate spreads, the risk of the portfolio would be 6.9 bp/month. We also see that both the Government-Related and Securitized sectors have nontrivial risk. Interestingly, this is inconsistent with the small interest-rate duration imbalance reported in Exhibit 47–3. Therefore, these sectors must have other sources of risk that are important. By bringing volatilities into the analysis, we can now compare and quantify the impact of each of the portfolio imbalances.

EXHIBIT 47–4

Isolated Risk per Category

Risk Factors Categories	Risk
Curve	11.3
Volatility	0.2
Spread Government-Related	3.2
Spread Corporate	6.9
Spread Securitized	2.9

Source: Barclays Capital POINT

2. For an explanation of Isolated TEV, see Chapter 46.

For future reference, let us compute the volatility of the portfolio assuming that all these sources of risk are independent (e.g., correlations are zero). This number is 13.9 bp/month.[3] Of course, this scenario is unrealistic, as these sources of risk are not independent. Also, this analysis does not allow us to understand the interplay between the different imbalances. For instance, we know that the isolated risk associated with the curve is 11.3 bp/month. But this value can be achieved both by being long or short interest-rate duration. So the isolated number does not allow us to understand the impact of the curve imbalance to the total risk of the portfolio. The net impact certainly depends on the sign of the imbalance. For instance, a long exposure in curve may be diversified away by a long exposure in credit (due to negative correlation between rates and credit-spreads). In contrast, an opposite (short) curve exposure would add to the risk of the long exposure in credit. The risk is clearly smaller in the first case.

To alleviate these shortcomings, we bring correlations into the picture. They allow us to understand the net impact of the various exposures to the portfolio's total risk and to detect potential sources of diversification among the portfolio imbalances. Exhibit 47–5 reports the contribution of each of the risk factor groups to the total risk, once all correlations are taken into account. We refer to this quantity as the contribution to tracking error volatility, or CTEV.[4] The total risk (10.4 bp/month) is smaller than the zero-correlation risk calculated before (13.9 bp/month) due to generally negative correlations between the curve and the spread factors. The exhibit also allows us to isolate the main contributors to risk as being curve (6.9 bp/month) and credit-spreads (2.9 bp/month), in line

EXHIBIT 47–5

Contributions to Total Risk per Category

Risk Factors Categories	Risk
Total	**10.4**
Curve	6.9
Volatility	0.7

Spread Corporate	0.0
Spread Securitized	2.9

Source: Barclays Capital POINT

3. We arrive at this number by taking the square root of the sum of squares of all the numbers in the table: $13.9 = \sqrt{(11.32+0.22+3.32+6.92+2.92)}$.
4. For a further discussion of this risk measure, see Chapter 46.

with the evidence from the earlier isolated analysis. However, the risk of the Government-Related and Securitized spreads is significantly smaller once correlations are taken into account.

The difference in analysis between the isolated risk reported in Exhibit 47–4 and the contributions to total risk in Exhibit 47–5 deserves further discussion. For simplicity, assume there are only two sources of risk in the portfolio—yield-curve (Y) and spreads (S). The total systematic variance of the portfolio (P) can be illustrated as follows:

$$\begin{aligned} VAR(P) &= VAR(Y+S) = VAR(Y) + VAR(S) + 2COV(Y, S) \\ &= Y \times Y + S \times S + 2(Y \times S) \end{aligned}$$

where we use the product to represent variances and covariances. Another way to represent this summation is using the following matrix:

$$\begin{bmatrix} Y \times Y & Y \times S \\ Y \times S & S \times S \end{bmatrix}$$

The sum of the four elements in the table is the variance of the portfolio. The isolated risk (in standard deviation units) reported in Exhibit 47–4 is the square root of the diagonal terms. So the isolated risk due to spreads is represented as:

$$Risk_{Spreads}^{Isolated} = \sqrt{S \times S}$$

It would be a function of the exposure to all spread factors, the volatilities of all these factors and the correlations among them.

The contribution to total risk reported in Exhibit 47–5 is:

$$Risk_{Spreads}^{Contribution} = [Y \times S + S \times S] / \sqrt{VAR(P)}$$

that is, from the matrix above, we sum all elements in the row of interest (row 1 for Y, row 2 for S), and normalize it by the standard deviation of the portfolio. This normalization (1) takes into account correlations and (2) ensures that the contributions to risk of all factors add up to the total risk of the portfolio given by[5]

$$Risk_{Curve}^{Contribution} + Risk_{Spreads}^{Contribution} = \sqrt{VAR(P)} = STD(P)$$

The difference between isolated and contribution to risk, due to the interplay of the two sources ($2(Y \times S)$), is allocated equally to each source of risk. In cases when one type of risk on isolated basis is much smaller in magnitude than the other, the ($Y \times S$) term may have an oversized effect. To summarize, isolated risk takes into account only the individual behavior of each source of risk, while the contribution to correlated risk looks at the joint behavior of various risk sources.

5. In this example, we focus only on the systematic component of risk. Later, the normalization is with respect to the total risk of the portfolio, including idiosyncratic risk.

The generic analysis we just performed constitutes the first step into the description of the risk associated with a portfolio. The analysis refers to categories of risk factors (such as "curve" or "spreads"). However, a factor-based risk model allows for a significantly deeper analysis of the imbalances the portfolio may have. Each of the risk categories referred to above can be described with a rich set of detailed risk factors. Typically in a fixed income factor model, each asset class has a specific set of risk factors, in addition to the potential set of factors common to all (e.g., curve factors). These asset-specific risk factors are designed to capture the particular sources of risk the asset class is exposed to. In the following section, we go through a risk report built in such a way, emphasizing risk factors that are common or particular to the different asset classes. Along the way, we demonstrate how the report offers insights from both a risk management and a portfolio construction perspective.

A Detailed Risk Report

In this section, we continue the analysis of the portfolio introduced previously, a 100-bond portfolio benchmarked against the Barclays Capital U.S. Aggregate Index. The report package we present was generated using POINT, Barclays Capital cross-asset portfolio analysis and construction tool, and gives a detailed picture of the risk embedded in the portfolio.[6] The package is divided into four types of reports: summary reports, factor exposure reports, issue/issuer level reports, and scenario analysis reports. Some of the information we reviewed earlier can be thought of as summary reports.

Summary Report

Exhibit 47–6 illustrates a typical risk summary statistics report. It shows that the portfolio has 100 positions, but from only 48 issuers. This number implies limited ability to diversify idiosyncratic risk, as we will see below. The report confirms that the portfolio is long interest-rate duration (5.36 years for the portfolio versus 4.98 years for the benchmark) and has higher yield (4.55% for the portfolio versus 2.97% for the benchmark) and coupon (5.07% for the portfolio versus 4.24% for the benchmark).

The exhibit also reports that the total volatility of the portfolio (127.7 bp/month) is higher than that of the benchmark (121.2 bp/month). This is not surprising: longer interest-rate duration, higher spread, and less diversification all tend to

6. The Barclays Capital Global Risk Model is available through POINT, Barclays Capital portfolio management tool. It is a multicurrency cross-asset model that covers many different asset classes across the fixed income and equity markets, including derivatives in these markets. At the heart of the model is a covariance matrix of risk factors. The model has several hundreds of factors, many specific to a particular asset class. The asset class models are periodically reviewed. Structure is imposed to increase the robustness of the estimation of such large covariance matrix. The model is estimated from historical data. It is calibrated using extensive security-level historical data and is updated on a monthly basis.

Source: Barclays Capital POINT

increase the volatility of a portfolio. Because of its higher volatility, we refer to the portfolio as riskier than the benchmark. Looking into the different components of the portfolio volatility, the exhibit reports that the idiosyncratic volatility of the portfolio is significantly smaller than that of the systematic one (10.5 bp/month versus 127.3 bp/month), which is what we expect from a medium-sized portfolio of investment-grade bonds.

Given the fact that the systematic and idiosyncratic components of risk are independent by construction, we can calculate the total volatility of the portfolio as

$$\text{TEV}_{Portfolio} = \sqrt{127.3^2 + 10.5^2} = 127.7$$

There are two interesting observations regarding this number:

1. The total volatility is smaller than the sum of the volatilities of the two components.
2. The total volatility is very close to the systematic one.

The first observation is the diversification benefit that comes from combining independent sources of risk. The second observation may suggest that the idiosyncratic risk is irrelevant. That is an erroneous and dangerous conclusion, as we will see later. In particular, when managing against a benchmark, the focus should be on the net exposures and risk, not on their absolute counterparts.

In Exhibit 47–6, the total TEV is reported as 14.2 bp/month. This means that the model forecasts the portfolio return to be typically around 14 bp/month higher than or lower than the return of the benchmark. This number is in line with the risk budget of the manager. The exhibit also reports idiosyncratic TEV of 9.6 bp/month, which is close in magnitude to the systematic TEV (10.4). Therefore, when measured against the benchmark, half of the risk is idiosyncratic, contrary to the conclusion one could draw by looking only at the portfolio's volatility. The TEV of the portfolio is also greater than the difference between the volatilities of the portfolio and benchmark. It would be equal to the difference only if the portfolio and benchmark were perfectly correlated.

Finally, the report shows that the portfolio has a beta of 1.05 to the benchmark. This statistic measures the co-movement between the portfolio and the benchmark. We can read it as follows: the model forecasts that a movement of 100 bp in the benchmark leads to a movement of 105 bp in the portfolio in the same direction. Note that a beta of less than one does not mean that the portfolio is less risky than the benchmark; it just means that the portfolio is less sensitive to movements in the benchmark. To see this more clearly, consider the limit case when the portfolio and benchmark are uncorrelated. The portfolio beta in this case is zero but obviously that does not mean that the portfolio has zero risk. Finally, one can compute many different "betas" for the portfolio or subcomponents of it.[7] A simple and widely used one is the "interest-rate duration beta," given by the ratio of the portfolio interest-rate duration to that of the benchmark. In our case this ratio is 5.36/4.98 = 1.08. This implies that the portfolio has a return from yield-curve movements around 1.08 times larger than that of the benchmark. This beta is larger than the portfolio beta (1.05), meaning that net exposures to other factors (e.g., spreads) "hedge" the portfolio's net curve risk.

7. For example, see Exhibit 47–13 later in this chapter.

This first summary report (Exhibit 47–6) allows the manager to get a glimpse into the risk of the portfolio. However, the manager wants to know in more detail what the sources of this risk are. Risk can be broken down along various dimensions, two of which we briefly looked at above: security groups (asset classes) and risk factors. The next two summary reports present the detailed risk breakdown along these two dimensions. In the first, risk is partitioned across different groups of risk factors. In the second, the partition is across groups of securities.

Exhibit 47–7 shows four different statistics associated with each set of risk factors. The first two were partly explored in Exhibits 47–4 and Exhibit 47–5.[8] The exhibit reports in the first column the isolated TEV, that is, the risk associated with that particular set of risk factors only. We see that in an isolated analysis, the systematic risk and idiosyncratic risk are balanced at 10.4 and 9.6 respectively.

The report also shows the isolated risk associated with the major components of systematic risk. As discussed before, all components of systematic risk have nontrivial isolated risk, but only curve and credit-spreads are relevant when we look into the CTEV. If we look across factors, the major contributors are idiosyncratic risk, curve, and credit-spreads. Other systematic exposures are relatively small.

Another look into the correlation comes when we analyze the liquidation effect reported in Exhibit 47–7. This number represents the change in TEV when we completely hedge that particular group of risk factors. For instance, if we

EXHIBIT 47–7

Factor Partition—Risk Analysis

Risk Factor Group	Isolated TEV(bp)	Contribution to TEV (CTEV)(bp)	Liquidation Effect on TEV(bp)	TEV Elasticity (%)
Total	**14.2**	**14.2**	**–14.2**	**100.0**
Systematic Risk	10.4	7.6	–4.5	53.8
Curve	11.3	5.6	–1.1	39.2
Volatility	0.2	0.0	0.0	0.1
Government-Related Spreads	3.2	0.0	0.4	0.1
Corporate Spreads	6.9	2.1	–0.5	15.1

8. Note that the contribution numbers are different than those from Exhibit 47–5, because there we were looking at the contribution to systematic—not total—risk.

hedge the curve component of the portfolio, the TEV drops by 1.1 bp/month—from 14.1 to 13.0. One may think that the drop is rather small given the magnitude of isolated risk the curve represents. However, if we hedge the curve, we also eliminate the risk reduction effect of the negative correlation between curve and spreads. Therefore, there is a more limited impact when hedging the curve risk than what is expected based on previous numbers. In fact, for this portfolio we see that hedging any particular set of risk factors has a limited effect on the overall risk.

The TEV elasticity reported in the last column gives another perspective into how the TEV changes when risk loadings change. Specifically, it tells the manager what the percentage impact on TEV is if the exposure to that particular set of factors is changed. For example, if the manager reduces the exposure to corporate spreads by 10%, the TEV would decrease by 10% × 15.1% = 1.51% and therefore it would become 14.2 bp × (1 – 1.51%) = 14.0 bp.

We perform a similar analysis in Exhibit 47–8, but apply it to a security partition. That is, instead of looking at individual sources of risk (e.g., curve) across all securities, we now aggregate all sources of risk within a security and report analytics for different groups of these securities (e.g., subportfolios). Exhibit 47–8 reports results when securities are grouped by asset class. It shows that the majority of risk (7.8 bp/month) comes from the Treasury component of the portfolio. Most of this risk is systematic, which is what we expect given the typically low idiosyncratic risk of the sector and the significant interest-rate duration mismatch. Corporates are also a major contributor to the portfolio's risk, mostly coming from idiosyncratic risk. This reflects the portfolio's large net

EXHIBIT 47–8

Security Partition—Risk Analysis I

		Contribution to TEV		
Security Partition Bucket	**NMW (%)**	**Systematic**	**Idiosyncratic**	**Total**
Total	**0.00**	**7.6**	**6.6**	**14.2**

CMBS	1.96	–0.2	0.6	**0.4**

Source: Barclays Capital POINT

market weight (NMW) to this sector. The lack of systematic risk contribution by the corporate sector comes from the hedging effect of spreads to the overall curve risk in the portfolio. Note that because the analysis is at the portfolio level, the interplay between net curve risk of Treasuries and spread risk of corporates is partly reflected in the total risk attributed to corporates. The same story applies to other spread sectors, all of which contribute little to systematic risk. Both agency MBS and CMBS contribute non-trivially to idiosyncratic risk. Since the portfolio manager's goal is the replication of a very large benchmark with only 100 positions, the manager has to be comfortable with the issuers selected. This report highlights the significant name risk to which the portfolio is exposed.

Exhibit 47–9 completes the analysis, reporting other important risk statistics about the different asset classes within the portfolio. These statistics mimic the analysis done in terms of risk factor partitions in Exhibit 47–7, so we will not repeat their definitions and focus on the results. Looking at isolated TEV, we see that Corporates have risk of 16.7 bp/month, which is higher than the total risk of the portfolio. This means that the exposures to the other asset classes, on average, hedge the Corporates portfolio. The same can be said about Treasuries. We can even take the analysis a bit further: the next column shows through the liquidation effect that if we eliminate the imbalance the portfolio has on Corporates, we actually would increase the total risk of the portfolio by 4.6 bp/month. In short, we would be eliminating the hedge this asset class provides to the global portfolio, therefore increasing its risk. Because a similar analysis holds for Treasuries, we can conclude that the exposures to Treasuries and Corporates were built to balance each other in the portfolio. Finally, Exhibit 47–9 also reports the TEV elasticity of the different components of the portfolio. This number represents how

EXHIBIT 47–9

Security Partition—Risk Analysis II

Security Partition Bucket	Isolated TEV	Liquidation Effect on TEV	TEV Elasticity (%)
Total	**14.2**	**–14.2**	**100.0**
Treasuries	18.8	4.1	53.2
Government Agencies	5.1	–0.9	12.2
Government Nonagencies	3.4	1.4	–7.5
Corporates	16.8	4.6	32.1

ABS	0.6	0.1	–0.3
CMBS	3.5	0.0	2.7

Source: Barclays Capital POINT

much a relative change in NMW translates into a relative change on TEV, so we need to read the numbers with an opposite sign if the NMW is negative. In particular, if we decrease the weight of the agency portfolio (making it more negative, or "more short") by 10%, we would actually increase the TEV by 10% × 12.2 % = 1.22% making it equal to 14.2 bp × (1 + 1.22%) = 14.4 bp. This result shows that the position in agencies provides hedging "on average," but further increasing the exposure to this sector would actually increase the risk of the portfolio. In other words, the hedging went beyond its optimal value.

This set of summary reports gives us a clear picture of the major sources of risk and how they relate to each other. In what follows, we focus on the more detailed analysis of the individual systematic sources of risk.

Factor Exposure Reports

At the heart of a multifactor risk model is the definition of the set of systematic factors that drive risk across the portfolio. As described in Chapter 46, there are many different types of risk sources a fixed income portfolio is exposed to. In what follows we focus on the three major types: curve, credit, and prepayment risk. To illustrate credit and prepayment risk, we use the Corporates component and the agency MBS component of the portfolio, respectively. Moreover, to keep the example simple, we show only a partial view of all relevant factors for these sources of risk.

Curve Risk Exhibit 47–10 details the risk in the portfolio associated with the U.S. Treasury curve. It starts by describing all risk factors the portfolio or benchmark load on. In particular, we use six key-rate (KR) points on the curve plus the convexity term as the risk factors associated with U.S. Treasury risk. They are described in the first column of panel A in the exhibit and measure the risk associated with moves of that particular point on the curve. Exposure to these risk factors is measured by the key-rate durations (KRD) for each of the six points. The description of the loading is in the exhibit's second column, while its value for the portfolio, benchmark, and the difference is displayed in the next columns. Key-rate durations are also called partial durations, as they add up to the interest-rate duration of the portfolio. For instance, for the portfolio, the sum of the key-rate durations is 0.13 + 0.47 + 1.74 + 0.93 + 1.00 + 1.09 = 5.36, the total interest-rate duration of the portfolio. Their loadings are constructed by aggregating partial durations across all the securities.

Looking at the exhibit, we see significant mismatches in the duration profiles between the portfolio and its benchmark, namely at the 10-year and 30-year points on the curve. Specifically, we are short 0.44 years at the 10-year point and long 0.41 years at the 30-year point. Moreover, we are also significantly long at the 5-year and 20-year points. How serious is this mismatch? Looking at the factor volatility column, it can be seen that these points on the curve have been fairly volatile at around 30 bp/month. If we interpret this volatility as a typical move, the first two columns of panel B show us the potential impact of such a movement in

EXHIBIT 47–10

Treasury Curve Risk

A. Exposures and Factor Volatility

Factor Name	Units	Exposure			Factor Volatility
		Portfolio	Benchmark	Net

the return of the portfolio, net of benchmark. For instance, a typical move up (+32.2 bp/month) in the 10-year point of the Treasury curve, when considered in isolation, will deliver a positive net return of +14.2 bp.[9] In isolation, the positive impact is expected because we are short that point of the curve. More interesting may be the correlated number on the exhibit. It states the return impact but in a correlated fashion. In the scenario under analysis, a movement in the 10-year point will almost surely involve a movement of the neighboring points on the curve. So contrary to the positive isolated effect documented above, the correlated impact of a change up in the 10-year point is actually negative, at –5.5 bp. This result is in line with the overall positive interest-rate duration exposure the portfolio has: general (correlated) movements up in the curve have a negative impact on the portfolio's performance.[10] As another expression of the high correlation among curve points, we can see that correlated changes on various points on the curve have a similar impact on the final portfolio, even though their associated exposures vary greatly. Finally, and broadly speaking, the ratio of the correlated impact to the factor volatility gives us the model-implied partial empirical interest-rate duration of the portfolio. For instance, if we focus on the 10-year point, we get 5.5/32.2 = 0.17. This smaller empirical interest-rate duration is typical in portfolios with spread exposure. This spread exposure tends to empirically hedge some of the curve exposure, given the negative correlation between these two sources of risk. In addition, Exhibit 47–10 shows the risk associated with convexity. We can see that the portfolio is long convexity while the benchmark is short, so higher order changes in the yield-curve have an opposite impact on the portfolio than on the benchmark.

There are many other statistics of interest one can analyze regarding the Treasury curve risk of the portfolio. The portfolio manager may ask questions such as: If I want to reduce the risk of my portfolio by manipulating my Treasury curve exposure, what could I change? What is the most effective move? By how much would my risk actually change? The statistics reported in columns "Marginal Contribution to TEV" and "TEV Elasticity (%)" of panel B are typically used to answer these questions. Regarding the marginal contributions, the 30-year point has the largest value, showing us that an increase (reduction) of one unit of exposure (in this case one year of duration) to the 30-year point leads to an increase (reduction) of 12.8 bp in the TEV.[11] In other

9. This number is obtained by simply multiplying the net exposure by the factor volatility. The sign of the move depends on the interpretation of the factor. In the case of the yield-curve movements, we know that $R = -KRD \times \Delta KR$, where KRD is the duration associated with the KR point. In our example – (–0.44) × 32.2 bp = +14.2 bp.
10. This reversal is clearly related to the fact that the 10-year point on the curve is usually highly correlated to the 5-, 20-, and 30-year ones. In our case, our short position on the 10-year point is more than compensated by the positive exposure to the other points in the curve. Netting out, the positive exposure effect (long duration) dominates when all changes are taken in a correlated fashion.
11. The marginal contribution is the derivative of the TEV with respect to the loading of each factor, so its interpretation holds only for small moves. Therefore, a more realistic reading may be that if we reduce the exposure to the 30-year by 0.1 years, the TEV would be reduced by around 1.3 bp.

words, if we want to reduce risk by manipulating the exposure to the yield-curve, the 30-year point seems to present the fastest track. In addition, the exhibit shows that all Treasury risk factors are associated with positive marginal contributions. This means that an increase in the exposure to any of these factors increases the risk (TEV) of the portfolio. This conclusion holds even for factors for which we have negative exposure (e.g., the 10-year key-rate) because increasing exposure to it means decreasing the negative exposure. To put it differently, the result is a consequence of the portfolio's overall long interest-rate duration exposure. Adding more duration exposure, regardless of the specific point where the manger does it, will result in an increase in portfolio risk.[12] This result holds because we take into consideration the correlations between the different points in the Treasury curve.

Exhibit 47–10 also reports the TEV elasticity of each of the risk factors, a concept introduced earlier. The interpretation is similar to the marginal contribution, but with normalized changes (percentage changes). This normalization makes the numbers more comparable across risk factors of very different nature. It is also useful when considering leveraging the entire portfolio proportionally. In our case, if we increase the exposure to the 10-year key-rate point by 10%, from –0.44 to –0.484 (effectively reducing the long interest-rate duration exposure), the TEV would be reduced by 3.79% (from 14.2 to 13.7 bp/month).

We now turn the analysis to the other component of the curve risk described above: the risk embedded into the portfolio exposure to swap spreads, that is, the differences between the swap and Treasury curves. Many securities trade against the swap curve, making it the natural choice as the base risk curve for those markets. To unify the analysis with markets that use Treasuries as the base curve, we break the swap curve into the Treasury curve (analyzed in Exhibit 47–10) and excess over the Treasury—the swap spread.[13]

All the securities that typically trade against the swap curve (e.g., corporates and securitized bonds) are exposed, in our methodology, to both Treasury and swap spread (SS) risk. The analysis of the latter follows very closely that of the Treasury curve, so we only highlight the major risk characteristics of the portfolio along this dimension. Exhibit 47–11 shows that in general the exposure to swap spreads is smaller than of the exposure to the Treasury curve. Remember that Treasuries do not load on this set of risk factors, so the market-weighted exposures are consequently smaller. Comparing the swap spread volatilities with those from the Treasury curve (see Exhibit 47–10), we can observe significant differences. Looking at the profile of factor volatilities, one can see that its term structure of volatilities is U-shaped, with the short-end being quite volatile and the 5-year point having the lowest volatility. This is typically the case during periods when liquidity risk is high. Regarding net exposures, the exhibit shows that the largest

12. This is a rationale similar to the one used before, where we see all correlated impact with the same sign.

13. For a more detailed discussion, see Chapter 46.

(Continued)

mismatch is at the 10-year point, where the portfolio is short by 0.35 years. Interestingly, this is not the most expensive mismatch in terms of risk: when looking at the last column, we see that we would be able to change risk the most by manipulating the short end of the exposure to the swap spread curve, namely the 6-month point.

The previous exhibits allow us to understand the portfolio exposures to the different types of curve risk and their impact both on the return and risk of portfolios. They also guide us regarding what changes we can introduce to modify the risk profile of the portfolio. We continue our analysis with sources of risk that are more specific to particular asset classes.

Credit Risk Credit risk may be analyzed along various dimensions such as geography, industry, debt seniority, credit rating, or spread level. As discussed in Chapter 46, a powerful determinant of credit risk of a bond for relatively short horizons is given by its *duration times its spread*, or DTS. Under this setting, the spread return of the security is given by the product of its DTS and the percentage change in its spread.[14]

Assuming that the percentage change in spread has similar statistical properties across a group of bonds, we can select this common component as one driver of systematic spread changes, giving rise to the *DTS systematic risk factor*. Apart from DTS, many other characteristics may explain systematic changes in spreads. Examples would be systematic differences along debt seniority or credit rating. However, these differences are typically well captured by the DTS levels of each security. Therefore, they do not justify risk factors in addition to the DTS. On the other hand, there are bonds with similar DTS that may behave very differently, depending on their geography or industries membership, for instance. This difference is relevant enough to grant the typical use of different risk factors across these dimensions. In the framework under analysis here, this is achieved by introducing several DTS factors, one for each combination of region and industry considered in the risk model.

The results of such an approach to the analysis of the portfolio in our example are displayed in Exhibit 47–12, which shows the typical industry risk factors associated with credit risk. The portfolio has exposure to a single region (U.S.) and has net positions in 27 industries, spanning all three major sectors: industrials (IND), Utilities (UTI), and Financials (FIN). We saw before that the portfolio has significant net exposure to Financials in terms of market weights (3.7%, see Exhibit 47–1). In terms of risk exposure, Exhibit 47–12 shows that the net DTS attached to the Banking industry is 0.62[15] clearly the highest across

14. More specifically Spread Return = $-SD \times \Delta S = -SD \times S \times (\Delta S/S) = -DTS \times \%\Delta S$, where SD stands for spread duration, S for spread, and Δ for change.

15. The DTS units used in the report are based on an OAS duration (OASD) stated in years and an OAS in percentage points. Therefore, a bond with an OASD = 5 and an OAS = 200 bp would have a DTS of 5 × 2 =10. The DTS industry exposures are the market-value weighted sum of the DTS of each security in that industry.

Source: Barclays Capital POINT

all sectors. However, the marginal contribution to TEV that comes from that industry is comparable to almost all other industries, even with ones that have an almost zero net exposures, such as Brokerage. This observation suggests that all these industries are close substitutes to each other in the context of the current portfolio.

Another interesting point is highlighted by the fact that the marginal contribution is negative for all industries, even though some (such as Retail and Healthcare) are significantly over-weighted. The analysis suggests that if we increase the risk exposure to them, the risk would actually decrease. This result is again driven by the strong negative correlation between spreads in these industries and the yield-curve. For example, the exposure in banking is partially hedging out the significant long interest-rate duration position. This kind of analysis is only possible by accounting for the correlations across factors, underscoring the importance of the quality of the correlation estimates used by the model.

Although the risk factors used to measure risk are predetermined in a given factor model, there is flexibility on the way the risk numbers can be aggregated and reported.[16] For example, the credit risk model used to generate the risk report presented in Exhibit 47–12 does not use credit ratings as drivers of systematic credit risk. Instead, it uses the DTS concept. However, once generated, the risk numbers can be reported using any portfolio partition.

As an example, Exhibit 47–13 shows the risk breakdown by rating. As reported in this exhibit, the majority of risk is coming from the AAA exposure (11.3 bp/month), the bucket with the biggest mismatch in terms of net weight (–12.1%). This bucket includes Treasury and government-related securities, sectors that are underweighted in the portfolio, leading to significant risk. This is even clearer when we look into the isolated TEV numbers. If the manager had mismatches only on AAA's, the portfolio risk would be 22.8 bp/month, instead of the actual 14.2: the other exposures hedge the risk from AAA's. This report also identifies the systematic betas associated with each of the rating sub-portfolios. These betas add up to the portfolio beta, when we use the portfolio weights (not NMW) as weights in the summation. For example, the exhibit allows us to infer that a movement of 10 bp in the benchmark leads to a 12.6 bp return in the AAA sub-component of the portfolio. On the other hand, the beta of 0.22 for the BAA2 component of the portfolio does not signal low volatility for this sub-portfolio. It indicates mainly low correlation with the benchmark, possibly a result of the significant role of idiosyncratic risk for this set of bonds. Systematic betas of zero identify buckets for which the portfolio has (close to) no holdings.

Prepayment Risk Most securitized bonds, such as MBS or asset-backed securities (ABS), have uncertain cash-flows due to the borrower's option to prepay the

16. For a detailed methodology on how to performed this customized analysis, see Antonio Silva, "Risk Attribution with Custom-Defined Risk Factors," Barclays Capital Publication, August 2009.

Source: Barclays Capital POINT

bond at any time. Interest rates strongly drive this prepayment behavior, as explained in Chapter 46, thus adding an extra channel of exposure to interest-rate risk that is absent from other bonds (e.g., corporate bonds with no optionality). Typically, interest and prepayment models can accommodate this feature only imperfectly. Moreover, there are other factors influencing prepayment risk. To accommodate these limitations, risk models incorporate other major characteristics that can be associated with prepayment risk. Examples are the program/term of the deal, if the bond is priced at discount or premium (i.e., if the coupon on the bond is bigger than the current mortgage rates) and how seasoned the bond is.

Exhibit 47–14 shows a potential set of risk factors that capture these characteristics. Programs identified as having different prepayment characteristics are the Conventional (FannieMae and FreddieMac) 30-year bonds (the base case used for the analysis), the 15-year Conventional bonds, as well as the Ginnie Mae 30- and 15-year bonds. The age of bonds is captured by factors distinguishing between new and aged (seasoned) deals. Finally, each bond is also classified by the price of the security—discount, current or premium. In this example there are no seasoned discounted bonds, suggesting that the market rates at the time of the analysis are at historical lows. In terms of risk exposures, the exhibit shows that

the manager is underweighting 15-year and over-weighting 30-year Conventional bonds (the base case).

Interaction between Sources of Risk So far we analyzed the major sources of spread risk: credit and prepayment. To do this, we conveniently used two asset classes—Corporates and Agency MBS, respectively—where one can argue that these sources of risk appear relatively isolated. However, recent developments have made clear that these sources of risk appear simultaneously in other major asset classes, including nonagency MBS, home equity loans, and CMBS.[17] When designing a risk model for a particular asset class, one should be able to anticipate the nature of the risks the asset class exhibits currently or may encounter in the future. The design and ability to segregate between different kinds of risk depends also on the multitude of the bond indicatives and analytics available to the researcher. For this last point, it is imperative that the portfolio manager understand the pricing model and assumptions made to generate the analytics typically used as inputs in a risk model. This allows the portfolio manager to fully understand the output of the model, as well as its applicability and shortcomings. Other sources of risk—for example, liquidity risk—may be important for particular fixed income portfolios. They were discussed in Chapter 46.

Issue-Level Reports

The previous analysis focused on the systematic sources of risk. We now turn our attention to the idiosyncratic or name-specific risk embedded in the portfolio. This risk measures the volatility the portfolio has because of events specific to the individual issues/issuers it holds. Therefore, idiosyncratic risk is independent across issuers and diversifies away as the number of issuers in the portfolio increases: events with negative impact for some issuers are canceled by events with positive impact for others. Even for medium-sized portfolios, the idiosyncratic risk may be a substantial component of the total risk. Exhibit 47–7 indicates that the idiosyncratic volatility is 10.5 bp/month, more than double the idiosyncratic volatility of the benchmark (4.7 bp/month). When looking at the tracking error volatility net of benchmark, Exhibit 47–6 shows that the idiosyncratic risk is 9.6 bp/month and close to the systematic component (10.4 bp/month). This means that a major component of the monthly net return is typically driven by events affecting only individual issuers. Therefore, monitoring these individual exposures is of particular importance.

The idiosyncratic risk of each bond is a function of two variables: its net market weight and its idiosyncratic volatility. This latter variable depends on the nature of the bond issuer. For instance, a bond from a distressed firm has much higher idiosyncratic volatility than one from a government-related agency.

17. For more discussion on this point, see Radu Gabudean, "US CMBS Risk Model," Barclays Capital Publication, October 2010.

Exhibit 47–15 provides a summary of the idiosyncratic risk for the top 10 positions by market weight in the manager's portfolio. Not surprisingly, seven out of 10 are Treasury or agency MBS securities, in line with the constitution of the index used as benchmark. Moreover, these positions have significant market weights, given that the portfolio contains only 100 positions. Even though we see large concentrations, the idiosyncratic TEV for these holdings is small, as they are not exposed to significant issuer risk. The last column of the exhibit shows that within this group the bonds with the highest idiosyncratic risk are corporate bonds, one issued by CVS Corporation (CVS) and another issued by Kennametal Inc. (KMT). This is not surprising, as these are the type of securities with larger event risk. Even within corporates, idiosyncratic risk can be quite diverse: in particular, it usually depends on the industry, spread duration, and level of distress of the issuer (usually proxied by rating, or by the spread of the bond). For instance, the net position for both the CVS and KMT bonds is similar (3.06% and 3.00% respectively), and even though their maturity is similar, the CVS bond spread is higher, resulting in higher idiosyncratic risk (3.5 versus 2.6 bp/month). To manage the idiosyncratic risk in the portfolio the portfolio manager should pay close attention to mismatches between the portfolio and benchmark for bonds with large spreads or long spread durations. These would tend to affect disproportionally the idiosyncratic risk of the portfolio.

Although important, the information in Exhibit 47–15 is not enough to fully assess the idiosyncratic risk embedded in the portfolio. For instance, a portfolio manager could buy credit protection on CVS through a credit default swap (CDS), thereby significantly reducing the exposure to this issuer's bond. The position reported in this exhibit would still look significant because the CDS protection would not be reflected in it.

A better way is to look at idiosyncratic risk at the issuer rather than at the issue level. While idiosyncratic risk is usually independent across issuers, one may not assume that the idiosyncratic risk of securities of the same issuer is uncorrelated because they are all subject to the same company-specific events. A good risk model should account for such correlation and try to quantify it for different issuer and security types. For example, all types of securities (bonds, equities, convertibles, etc.) of an issuer in financial distress tend to move in a correlated fashion because they all represent claims to the same distressed assets. Adding more securities from such an issuer to a portfolio does not generally deliver additional diversification. On the other hand, securities from issuers in strong financial health can move quite differently from each other, driven primarily by liquidity or capital structure effects rather than credit. In this case, a portfolio manager can achieve some diversification of idiosyncratic risk (although limited) even when adding issues from that same issuer into the portfolio.

In order to understand the net effect of all such interactions, it is useful to review the contributions of individual issuers to the portfolio's total idiosyncratic risk. When aggregating risk from the issue (as shown in Exhibit 47–15) to the issuer level, the correlations referred to above should be fully taken into account.

Exhibit 47–16 shows the results of this exercise for the 10 issuers with the highest isolated idiosyncratic TEV. The riskiest issuer exposure in the portfolio comes from Mellon Capital, with isolated idiosyncratic risk of 4.0 bp/month. Note that no single security from this issuer appears as a top holding in the portfolio (see Exhibit 47–15). This highlights the importance of aggregating idiosyncratic risk at the issuer level. We can also observe that idiosyncratic TEV is not monotonic in the NMW: Mellon Capital and Ameren Corp have similar NMW, but the former is significantly riskier (4.0 versus 1.3 bp/month). It is also possible to have important idiosyncratic risk even for issuers the portfolio does not hold, namely for bonds from issuers that have significant market weight in the benchmark.

Finally, note that because the idiosyncratic risk across issuers is independent, the cumulative risk of several issuers can be easily calculated. For example, the total idiosyncratic risk of the top two issuers in Exhibit 47–16 is given by:

$$\text{TEV}_{idio}^{BK+GS} = \sqrt{4.0^2 + 3.5^2} = 5.3$$

As is the case in most portfolios tracking a benchmark, most issuers present in the portfolio are over-weighted relative to the benchmark. This is a natural

EXHIBIT 47–16

Source: Barclays Capital POINT

consequence of the fact that, in practice, portfolios hold far fewer positions than the benchmark. It may be difficult for the manager to hold positive views in all issuers selected in the portfolio. In fact, some of these positions may be selected to build exposure to specific systematic factors, such as a particular industry or asset class, and not to a particular issuer. However, it is important that the manager hold positive views for the issuers with the largest contribution to idiosyncratic risk. If this is not the case, then the manager is assuming a significant unintended name risk that should be promptly taken out of the portfolio, in favor of another issuer with similar characteristics for which the manager does have a positive view. This interactive exercise can easily be performed with a good and flexible portfolio construction tool and the help of an optimizer.

Scenario Analysis Report

Scenario analysis provides an additional perspective on the portfolio's risk. This exercise can be performed in several ways. For instance, a manager may want to reprice the whole portfolio under a particular scenario on risk factors, such as interest rates or spreads, and look at the hypothetical return under that scenario. Alternatively, a portfolio manager may wish to evaluate how the portfolio would have performed under particular historical scenarios (e.g., the 1987 equity crash or the Asian crisis in 1997). One particular problem with this approach is the fact that, given the dynamic nature of the securities, the current portfolio with its current characteristics did not exist during such historical episodes. Some of the portfolio securities may have not even been issued during such periods. A solution might be to price the current securities with the market variables at the time. While a valid solution, it is difficult to implement because pricing models require inputs possibly not available during that historical period.

EXHIBIT 47–17

Historical Systematic Simulated Returns (basis points)

Source: Barclays Capital POINT

An alternative is to represent the current portfolio as the set of loadings to all systematic risk factors in a linear factor risk model. We can then multiply these loadings by the historical realizations of the risk factors. The result is a set of historical systematic simulated returns. Exhibit 47–17 presents monthly returns for the period between December 2003 and December 2010. The dark line represents the absolute portfolio returns and the lighter line represents the portfolio's return net of the benchmark. Note that this analysis uses only one set of static portfolio loadings. Therefore, these simulated returns can be interpreted as the hypothetical returns a portfolio with these characteristics would have, if submitted to the historical episodes. As expected, the largest volatility was realized during the crisis of 2007–2009, when the portfolio registered returns between –300 and 400 bp. The largest underperformance against the benchmark occurred in November 2007 at about –25 bp, followed by other months during the crisis such as February and September 2008. The largest outperformance (about +30 bp) was registered at the end of 2008, when the portfolio—being long interest-rate duration—benefited from the sharp drop in interest rates registered during that period.

This analysis has some limitations, especially for the portfolio under analysis, where idiosyncratic exposure is a major source of risk. This kind of risk is always hard to capture and obviously less relevant from an historical perspective, as the issuers in the current portfolio may have not witnessed any particular major idiosyncratic event in the past. However, these and other types of historical scenario analyses are important, because they give managers some indication of the magnitude of historical returns the portfolio might have encountered. They are usually the starting point for any scenario analysis. The manager should always complement them with other non-historical scenarios relevant for the particular portfolio under analysis. In particular, the risk model can be used to express such scenarios, as discussed in Chapter 46.

KEY POINTS

- A good risk model provides detailed information about the exposures of a portfolio. Risk analysis starts with weight imbalances in the portfolio, when compared to the benchmark. For fixed income portfolios, the analysis of market weights has to be complemented with other analytics for a better description of the portfolio's exposure to the different sources of risk.
- The relevance of a risk source is given by the product of its volatility—how risky it is—and the portfolio's exposure to it. To get an aggregated description of risk, we have to bring into the analysis correlations between the different risk sources the portfolio is exposed to. The combination of these elements results in the overall risk of a portfolio versus a benchmark, or it's tracking error volatility.

- There are many different ways to analyze the risk of a portfolio. We can do it by type of risk factor (e.g., interest-rate risk) or by type of security (e.g., corporates). Many different metrics—such as contribution to TEV, liquidation effect on TEV or TEV elasticity—can provide further understanding of the overall risk of the portfolio.
- Risk analysis can be significantly enhanced using scenario analysis. There are several methods to perform it. One method is to look at the historical performance of a theoretical portfolio with constant loadings. This analysis allows a manager to study the potential behavior of a portfolio with such characteristics across major historical events.

CHAPTER
FORTY-EIGHT

HEDGING INTEREST-RATE RISK WITH TERM-STRUCTURE FACTOR MODELS

Portfolio managers seek to control or hedge the change in the value of a bond position or a bond portfolio to changes in risk factors. The relevant risk factors can be classified into two types: *term-structure risk factors* and *non-term-structure risk factors*. The former risks include parallel and nonparallel shifts in the term structure. Non-term-structure risk includes sector risk, quality risk, and optionality risk. Multifactor risk models that focus only on hedging exposure to interest-rate risks are referred to as the *term-structure factor model*.

Exposure to changes in interest rates is most often measured in terms of a bond or portfolio's *duration*. This is a one-dimensional measure of the bond's sensitivity to interest-rate movements. There is one complication, however: the value of a bond, or a bond portfolio, is affected by changes in interest rates of all possible maturities (i.e., changes in the term structure of interest rates). In other words, there is more than one risk factor that affects bond returns, and simple methods based on a one-dimensional measure of risk such as duration will not

allow portfolio managers to manage interest-rate risks properly.[1] Hence the need for term-structure factor models.

In this chapter we show how term-structure factor models can be used in interest-rate risk management. These models have been designed to better account for the complex nature of interest-rate risk. Because it is never easy to hedge the risk associated with too many sources of interest-rate uncertainty, it is always desirable to try to reduce the number of term-structure risk factors and identify a limited number of common factors. There are several ways in which this can be done, and it is important to know the exact assumptions one has to make in the process and try to evaluate the robustness of these assumptions with respect to the specific scenario a portfolio manager has in mind.

We first briefly review the traditional duration hedging method, which is still used heavily in practice and has been illustrated in several chapters in this book. The approach is based on a series of very restrictive and simplistic assumptions, including the assumptions of a small and parallel shift in the yield-curve. We then show how to relax these assumptions and implement hedging strategies that are robust with respect to a wider set of possible yield-curve changes. We conclude by analyzing the performance of various hedging techniques in a realistic situation, and we show that satisfying hedging results can be achieved by using a three-factor model for the yield-curve dynamics.

DEFINING INTEREST-RATE RISK(S)

The first fundamental fact about interest-rate risk management can be summarized by the following statement: bond prices move inversely to market yields.[2] More generally, we define as interest-rate risk the potential impact on a bond portfolio value of any given change in the location and shape of the yield-curve.

To further illustrate the notion of interest-rate risk, we consider a simple experiment. A portfolio manager wishes to hedge the value of a bond portfolio that delivers deterministic cash-flows in the future, typically cash-flows from fixed-coupon Treasury securities. Even if these cash-flows are known in advance, bond prices change in time, which leaves an investor exposed to a potentially significant capital loss.

To fix the notation, we consider at date t a bond (or a bond portfolio) that delivers m certain cash-flows CF_i at future dates t_i, for $i = 1, \ldots, m$. The price V

1. This complication is not specific to the fixed income environment. In the world of equity investment, it has actually long been recognized that there may be more than one rewarded risk factor that affects stock returns. A number of more general multifactor models, economically justified either by equilibrium or arbitrage arguments, have been applied for risk management and portfolio performance evaluation.
2. There are some derivative mortgage products that do not possess this property.

of the bond (expressed as a percentage of the face value) can be written as the sum of the future cash-flows discounted with the appropriate zero-coupon rate with maturity corresponding to the maturity of the cash-flows.

$$V_t = \sum_{i=1}^{m} \frac{CF_i}{[1 + R(t, t_i - t)]^{t_i - t}} \tag{48–1}$$

where $R(t, t_i - t)$ is the associated zero-coupon rate, starting at date t for a remaining maturity of $t_i - t$ years.

We see in Eq. (48–1) that the price V_t is a function of m interest-rate variables $R(t, t_i - t)$. This suggests that the value of the bond is subject to a potentially large number m of risk factors. For example, the price of a bond with annual cash-flows up to a 10-year maturity is affected by potential changes in 10 zero-coupon rates (i.e., the term structure of interest rates). To hedge a position in this bond, we need to be hedged against a change of all 10 of these risk factors.

In practice, it is not easy to perform risk management in the presence of many risk factors. In principle, one must design a *global portfolio* in such a way that the portfolio is insensitive to all sources of risk (the m interest-rate variables and the time variable t).[3] A global portfolio is one that contains the original portfolio plus any hedging instruments used to control the original portfolio's interest-rate risk. One suitable way to simplify the problem is to reduce the number of risk factors. Everything we cover in this chapter can be seen as a variation on the theme of reducing the dimensionality of the interest-rate risk-management problem.

We first consider the simplest model for interest-rate risk management, also known as *duration hedging*, which is based on a single risk variable, the yield-to-maturity of this portfolio.

HEDGING WITH DURATION

The intuition behind duration hedging is to bypass the complexity of a multidimensional interest-rate risk by identifying a single risk factor that will serve as a "proxy" for the whole term structure. The proxy measure used is the yield of a bond. In the case of a bond portfolio, it is the average portfolio yield.

3. In this chapter we do not consider the change of value owing to time because it is a deterministic term. We only consider changes in value owing to interest-rate variations. For details about the time value of a bond, see Don M. Chance and James V. Jordan, "Duration, Convexity, and Time as Components of Bond Returns," *Journal of Fixed Income* (September 1996), pp. 88–96.

First Approximation: Using a One-Order Taylor Expansion

The first step consists in writing the price of the portfolio V_t (in percent of the face value) as a function of a single source of interest-rate risk, its yield-to-maturity y_t, as shown below:

$$V_t = V(y_t) = \sum_{i=1}^{m} \frac{CF_i}{(1+y_t)^{t_i - t}} \tag{48–2}$$

In this case, we can see clearly that the interest-rate risk is (imperfectly) summarized by changes of the yield-to-maturity y_t. Of course, this can only be achieved by losing much generality and imposing important, rather arbitrary and simplifying assumptions. The yield-to-maturity is a complex average of the entire term structure, and it can only be assimilated to the term structure if the term structure happens to be flat (i.e., the yield-to-maturity is the same for each maturity).

A second step involves the derivation of a *Taylor expansion* of the value of the portfolio V as an attempt to quantify the magnitude of value changes that are triggered by small changes y in yield. Before showing how this is done, let's briefly review what a Taylor expansion is. A Taylor expansion is a tool used in calculus to approximate the change in the value of a mathematical function owing to a change in a variable. The change can be approximated by a series of "orders," with each order related to the mathematical derivative of the function. When one refers to approximating a mathematical function by a first derivative, this means using a Taylor expansion with only the first order. Adding to the approximation from the second order to the approximation from the first order improves the approximation.

Let us return now to approximating the change in value of a bond when interest rates change. The mathematical function is Eq. (48–2), the value of a bond portfolio. The function depends on the yield. We denote dV as the change in the value of the portfolio triggered by small changes in yield denoted by dy. The approximate *absolute* change in the value of the portfolio triggered by small changes in yield in using a Taylor expansion is

$$dV(y) = V(y+dy) - V(y) = V'(y)dy + o(y) \approx \$\text{dur}[V(y)]dy \tag{48–3}$$

where

$$V'(y) = -\sum_{i=1}^{m} \frac{(t_i - t)F_i}{(1+y_t)^{t_i - t + 1}}$$

which is the derivative of the bond value function with respect to the yield-to-maturity. This value is known as the *dollar duration of the portfolio V*, denoted by \$duration, and $o(y)$ a negligible term.

Dividing Eq. (48–3) by $V(y)$, we obtain an approximation of the *relative* change in value of the portfolio as

$$\frac{dV(y)}{V(y)} = \frac{V'(y)}{V(y)} dy + o_1(y) \approx -MD[V(y)]dy \tag{48–4}$$

where $MD\ [V(y)] = -[V'(y)/V(y)]$ is known as the *modified duration of portfolio V.*

The \$duration and the modified duration enable us to compute the absolute profit and loss for the portfolio (absolute P&L) and relative P&L of portfolio V for a small change Δy of the yield-to-maturity. That is,

$$\text{Absolute P\&L} \approx N_V \times \$\text{dur} \times \Delta y$$
$$\text{Relative P\&L} \approx -MD \times \Delta y$$

where N_V is the face value of the portfolio.

Performing Duration Hedging

We attempt to hedge a bond portfolio with face value N_V, yield-to-maturity y, and price denoted by $V(y)$. The idea is to consider one hedging instrument with face value N_H, yield-to-maturity y_H (*a priori* different from y), whose price is denoted by $H(y_H)$ and build a global portfolio with value V^* invested in the initial portfolio and some quantity ϕ of the hedging instrument.

$$V^* = N_V V(y) + \phi N_H H(y_H)$$

The goal is to make the global portfolio insensitive to small interest-rate variations. Using Eq. (48–3) and assuming that the yield-to-maturity curve is only affected by parallel shifts so that $dy = dy_H$, we obtain

$$dV^* \approx [N_V V'(y) + \phi N_H H'(y_H)]dy = 0$$

which translates into

$$\phi N_H \$\text{dur}[H(y_H)] = -N_V \$\text{dur}[V(y)]$$
$$\phi N_H H(y_1) MD[H(y_H)] = -N_V V(y) MD[V(y)]$$

so that we finally get

$$\phi = -\frac{N_V \$\text{dur}[V(y)]}{N_H \$\text{dur}[H(y_H)]} = -\frac{N_V V(y) MD[V(y)]}{N_H H(y_1) MD[H(y_H)]} \tag{48–5}$$

The optimal amount invested in the hedging instrument is simply equal to the opposite of the ratio of the \$duration of the bond portfolio to hedge by the \$duration of the hedging instrument when they have the same face value.

When the yield-curve is flat, which means $y = y_H$, Eq. (48–5) simplifies to

$$\phi = -\frac{N_V V(y) D[V(y)]}{N_H H(y) D[H(y)]}$$

where the Macaulay duration $D[V(y)]$ is defined as

$$D[V(y)] = -(1+y)MD[V(y)] = \frac{\sum_{i=1}^{m} \frac{(t_i - t)F_i}{(1+y)^{t_i - t}}}{V(y)}$$

In practice, it is preferable to use futures contracts or swaps instead of bonds to hedge a bond portfolio because of significantly lower costs and higher liquidity. For example, using futures as hedging instruments, the hedge ratio ϕ_f is equal to

$$\phi_f = -\frac{N_V \$\text{dur}_V}{N_F \$\text{dur}_{CTD}} \times cf \tag{48–6}$$

where N_F is the size of the futures contract. $\$\text{dur}_{CTD}$ is the \$duration of the cheapest to deliver, and cf is the conversion factor.

Using standard swaps, the hedge ratio ϕ_s is

$$\phi_s = -\frac{N_V \$\text{dur}_V}{N_S \$\text{dur}_S} \tag{48–7}$$

where N_S is the nominal amount of the swap, and $\$\text{dur}_S$ is the \$duration of the fixed-coupon bond forming the fixed leg of the swap contract.[4]

Duration hedging is very simple. However, one should be aware that the method is based on the following, very restrictive assumptions:

- It is explicitly assumed that the value of the portfolio could be approximated by its first-order Taylor expansion. This assumption is all the more disputable that changes of the interest rates are larger. In other words, the method relies on the assumption of small yield-to-maturity changes. This is why the hedging portfolio should be readjusted reasonably often.
- It is also assumed that the yield-curve is only affected by parallel shifts. In other words, interest-rate risk simply is considered as a risk on the general level of interest rates.

In what follows, we attempt to relax both assumptions to account for more realistic changes in the term structure of interest rates.

RELAXING THE ASSUMPTION OF A SMALL SHIFT

We have argued that \$duration provides a convenient way to estimate the impact of a *small* change dy in yield on the value of a bond or a portfolio.

Using a Second-Order Taylor Expansion

Duration hedging only works effectively for small yield changes because the price of a bond as a function of yield is nonlinear. In other words, the \$duration of a bond changes as the yield changes. When a portfolio manager expects a potentially large

4. For examples of hedging with futures, see Chapter 61. For examples of hedging portfolios constructed with futures contracts and swaps, see Lionel Martellini, Philippe Priaulet, and Stephane Priaulet, *Fixed Income Securities: Valuation, Risk Management and Portfolio Strategies* (Chichester, England: Wiley, 2003).

shift in the term structure, a convexity term should be introduced, and the price change approximation can be improved if one can account for such nonlinearity by explicitly introducing the convexity term.

Let us take the following example to illustrate this point. We consider a 10-year maturity and 6% annual coupon bond trading at par. Its modified duration and convexity are equal to 7.36 and 57.95, respectively.[5] We assume that the yield-to-maturity goes suddenly from 6% to 8%, and we reprice the bond after this large change. The new price of the bond, obtained by discounting its future cash-flows, is now equal to \$86.58, and the exact change in value amounts to –\$13.42 (= \$86.58 – \$100). Using a first-order Taylor expansion, the change in value is approximated by –\$14.72 (= –\$100 × 7.36 × 0.02), which overestimates the decrease in price by \$1.30. We conclude that a first-order Taylor expansion does not provide us with a good approximation of the bond price change when the variation of its yield-to-maturity is large.

If a portfolio manager is concerned about the impact of a larger move dy on a bond portfolio value, one needs to use (at least) a second-order version of the Taylor expansion as given below.

$$\begin{aligned} dV(y) &= V'(y)dy + \frac{1}{2}V''(y)(dy)^2 + o[(dy)^2] \\ &\approx \$\mathrm{dur}[V(y)]dy + \frac{1}{2}\$\mathrm{conv}[V(y)](dy)^2 \end{aligned} \tag{48–8}$$

where the quantity V'' also denoted \$conv[$V(y)$] is known as the \$convexity of the bond V.

Dividing Eq. (48–8) by $V(y)$, we obtain an approximation of the relative change in value of the portfolio as

$$\frac{dV(y)}{V(y)} \approx -MD[V(y)]dy + \frac{1}{2}RC[V(y)](dy)^2$$

where $RC[V(y)]$ is called the (relative) *convexity of portfolio V*.

We now reconsider the preceding example and approximate the bond price change by using Eq. (48–8). The bond price change is now approximated by –\$13.56 [= –14.72 + (100 × 57.95 × 0.02²/2)]. We conclude that the second-order approximation is better suited for larger interest-rate deviations.

Performing Duration/Convexity Hedging

Hedging by taking into consideration first and second orders is called *duration/convexity hedging*. To perform a duration/convexity hedge, a portfolio manager needs to introduce two hedging instruments. We denote the value of the two hedging instructions by H_1 and H_2. The goal is to obtain a portfolio that is both

5. Note that convexity can be scaled in various ways.

$duration-neutral and $convexity-neutral. The optimal quantity (ϕ_1, ϕ_2) of these two hedging instruments to hold is then given by the solution to a system of equations at each date, assuming that $dy = dy_1 = dy_2$. The system of equations consists of two equations and two unknowns and can be solved easily algebraically.

More formally, the sytem of equations is

$$\begin{cases} \phi_1 N_{H_1} H_1'(y_1) + \phi_2 N_{H_2} H_2'(y_2) = -N_V V'(y) \\ \phi_1 N_{H_1} H_1''(y_1) + \phi_2 N_{H_2} H_2''(y_2) = -N_V V''(y) \end{cases}$$

which can be rewritten as:

$$\begin{cases} \phi_1 N_{H_1} \$\text{dur}[H_1(y_1)] + \phi_2 N_{H_2} \$\text{dur}[H_2(y_2)] = -N_V \$\text{dur}[V(y)] \\ \phi_1 N_{H_1} \$\text{conv}[H_1(y_1)] + \phi_2 N_{H_2} \$\text{conv}[H_2(y_2)] = -N_V \$\text{conv}[V(y)] \end{cases} \tag{48–9}$$

or

$$\begin{cases} \phi_1 N_{H_1} H_1(y_1) MD[H_1(y_1)] + \phi_2 N_{H_2} H_2(y_2) MD[H_2(y_2)] = -N_V V(y) MD[V(y)] \\ \phi_1 N_{H_1} H_1(y_1) RC[H_1(y_1)] + \phi_2 N_{H_2} H_2(y_2) MD[H_2(y_2)] = -N_V V(y) RC[V(y)] \end{cases}$$

RELAXING THE ASSUMPTION OF A PARALLEL SHIFT

Duration and duration/convexity hedging are based on single-factor models because only one interest rate is being considered. In this section we look at how we can go beyond a single-factor model to a term-structure factor model.[6]

Accounting for the Presence of Multiple Risk Factors

A major shortcoming of single-factor models is that they imply that all possible zero-coupon rates are perfectly correlated, making bonds redundant assets. We know, however, that rates with different maturities do not always change in the same way. In particular, long-term rates tend to be less volatile than short-term rates. An empirical analysis of the dynamics of the interest-rate term structure suggests that two or three factors account for most of the yield-curve changes. They can be interpreted, respectively, as level, slope and curvature factors (see below). This strongly suggests that a term-structure factor model should be used for pricing and hedging fixed income securities.

There are different ways to generalize duration hedging to account for nonparallel deformations of the term structure. The common principle behind all techniques is the following. Going back to Eq. (48–1), let us express the value of the portfolio using the entire curve of zero-coupon rates, where we now

6. See also Lionel Martellini, Philippe Priaulet, and Stephane Priaulet, "Beyond Duration," *Journal of Bond Trading and Management* (October 2002), pp. 103–119.

make explicit the time dependency of the variables. Hence we consider V_t to be a function of the zero-coupon rates $R(t, t_i - t)$. The risk factor is the yield-curve as a whole, *a priori* represented by m components, as opposed to a single variable, the yield-to-maturity y.

The main challenge is then to narrow down this number of factors in the least arbitrary way. The good news is that one can show that a limited number (two or three) of suitably designed risk factors can account for a large fraction of the information in the whole term yield-curve dynamics. There is actually a systematic method that allows us to achieve this very objective through what is known as a *principal components analysis* (PCA) of interest-rate changes, as will now be explained. This arguably has become the state-of-the-art technique for interest-rate risk management.

Regrouping Risk Factors through a Principal Component Analysis

The purpose of PCA is to explain the behavior of observed variables using a smaller set of unobserved, implied variables. From a mathematical standpoint, it consists of transforming a set of m correlated variables into a reduced set of orthogonal variables that reproduce the original information present in the correlation structure. This tool can yield interesting results, especially for the pricing and risk management of correlated positions. Using PCA with historical zero-coupon rate curves in major bond markets, it has been observed that the first three principal components of spot-curve changes, which can be interpreted as level, slope, and curvature factors, explain the main part of the returns variations on fixed income securities over time. More specifically, studies of spot rates in the U.S., German, Italian, French, Swiss, and Belgium government bond markets, found that at least 90% of the variation in returns can be explained by the three factors. The level component was the first factor which explained from 59% to 93% of the return variation. [7]

Using a PCA of the yield-curve, we may now express the change $dR(t, \theta_k) = R(t+1, \theta_k) - R(t, \theta_k)$ of zero-coupon rate $R(t, \theta_k)$ with maturity θ_k at

date t as a function of changes in the principal components (unobserved implicit factors)

$$dR(t,\theta_k) = \sum_{l=1}^{m} c_{lk} C_t^l + \varepsilon_{tk}$$

where c_{lk} is the sensitivity of the kth variable to the lth factor, defined as

$$\frac{\Delta\,[dR(t,\theta_k)]}{\Delta(C_t^l)} = c_{lk}$$

which amounts to individually applying a, say, 1% variation to each factor and computing the absolute sensitivity of each zero-coupon yield-curve with respect to that unit variation.

These sensitivities are commonly called the *principal component $durations*. C_t^l is the value of the lth factor at date t, and ε_{tk} is the residual part of $dR(t,\theta_k)$ that is not explained by the factor model.

One can easily see why this method has become popular. Its main achievement is that it allows for the reduction of the number of risk factors with an optimally small loss of information. Since these three factors (parallel movement, slope oscillation, and curvature), regarded as risk factors, explain most of the variance in interest-rate changes, we may now use not more than three hedging instruments. We now write the changes of value of a fixed income portfolio as

$$dV_t^* \approx \sum_{k=1}^{m}\left[\frac{\partial V_t}{\partial R(t,\theta_k)} + \sum_{j=1}^{3}\phi_t^j\,\frac{\partial H_t^j}{\partial R(t,\theta_k)}\right] dR(t,\theta_k)$$

We then use $dR(t,\theta_k) \approx \Sigma_{l=1}^{3} c_{lk} C_t^l$ to obtain

$$dV_t^* \approx \sum_{k=1}^{m}\left\{\left[\frac{\partial V_t}{\partial R(t,\theta_k)} + \sum_{j=1}^{3}\phi_t^j\,\frac{\partial H_t^j}{\partial R(t,\theta_k)}\right]\sum_{l=1}^{3} c_{lk} C_t^l\right\}$$

or

$$\begin{aligned} dV_t^* \approx & \sum_{k=1}^{m}\left[c_{1k}\,\frac{\partial V_t}{\partial R(t,\theta_k)} + \sum_{j=1}^{3}\phi_t^j c_{1k}\,\frac{\partial H_t^j}{\partial R(t,\theta_k)}\right] C_t^1 \\ & + \sum_{k=1}^{m}\left[c_{2k}\,\frac{\partial V_t}{\partial R(t,\theta_k)} + \sum_{j=1}^{3}\phi_t^j c_{2k}\,\frac{\partial H_t^j}{\partial R(t,\theta_k)}\right] C_t^2 \\ & + \sum_{k=1}^{m}\left[c_{3k}\,\frac{\partial V_t}{\partial R(t,\theta_k)} + \sum_{j=1}^{3}\phi_t^j c_{3k}\,\frac{\partial H_t^j}{\partial R(t,\theta_k)}\right] C_t^3 \end{aligned}$$

The first term in this expression is commonly called the *principal component $duration* of portfolio V^* with respect to factor 1.

If we want to set the (first order) variations of the hedged portfolio V_t^* to zero for any possible change in interest rates $dR(t,\theta_k)$ or, equivalently, for any possible evolution of the C_t^l terms, we may take as a sufficient condition, for $l = 1, 2, 3$,

$$\sum_{k=1}^{m}\left[c_{lk}\frac{\partial V_t}{\partial R(t,\theta_k)}+\sum_{j=1}^{3}\phi_t^j c_{lk}\frac{\partial H_t^j}{\partial R(t,\theta_k)}\right]=0$$

This is a neutral principal component $durations objective.

Finally, on each possible date, we are left with three unknowns ϕ_t^j and three linear equations. Let us introduce the following matrix notation

$$H_t'=\begin{pmatrix}\sum_{k=1}^{m}c_{1k}\frac{\partial H_t^1}{\partial R(t,\theta_k)} & \sum_{k=1}^{m}c_{1k}\frac{\partial H_t^2}{\partial R(t,\theta_k)} & \sum_{k=1}^{m}c_{1k}\frac{\partial H_t^3}{\partial R(t,\theta_k)}\\ \sum_{k=1}^{m}c_{2k}\frac{\partial H_t^1}{\partial R(t,\theta_k)} & \sum_{k=1}^{m}c_{2k}\frac{\partial H_t^2}{\partial R(t,\theta_k)} & \sum_{k=1}^{m}c_{2k}\frac{\partial H_t^3}{\partial R(t,\theta_k)}\\ \sum_{k=1}^{m}c_{3k}\frac{\partial H_t^1}{\partial R(t,\theta_k)} & \sum_{k=1}^{m}c_{3k}\frac{\partial H_t^2}{\partial R(t,\theta_k)} & \sum_{k=1}^{m}c_{3k}\frac{\partial H_t^3}{\partial R(t,\theta_k)}\end{pmatrix}$$

$$\Phi_t=\begin{pmatrix}\phi_t^1\\ \phi_t^2\\ \phi_t^3\end{pmatrix}\qquad V_t'=\begin{pmatrix}-\sum_{k=1}^{m}c_{1k}\frac{\partial V_t}{\partial R(t,\theta_k)}\\ -\sum_{k=1}^{m}c_{2k}\frac{\partial V_t}{\partial R(t,\theta_k)}\\ -\sum_{k=1}^{m}c_{3k}\frac{\partial V_t}{\partial R(t,\theta_k)}\end{pmatrix}$$

We then have the system

$$H_t'\Phi_t = V_t'$$

The solution is given by

$$\Phi_t = (H_t')^{-1}V_t'$$

In practice, one needs to estimate the principal components $durations used at date t. They are derived from a PCA performed on a period prior to t, for example, [t – 3 months, t]. As a result, the output of the method becomes strongly sample-dependent. In an attempt to alleviate this concern over robustness, it is actually more convenient to use a suitable functional specification for the zero-coupon yield-curve, provided that it is consistent with results from a PCA.

Hedging Using a Three-Factors Model of the Yield-Curve

The idea here consists of using a model for the zero-coupon rate function. We detail below the Nelson and Siegel model,[8] as well as the Svensson (or extended Nelson and Siegel) model.[9] One may alternatively use the Vasicek model,[10] the extended Vasicek model, or the Cox-Ingersoll-Ross (CIR) model,[11] among many others.[12]

Nelson-Siegel and Svensson Models

Nelson and Siegel suggested modeling the continuously compounded zero-coupon rates $R^c(0, \theta)$ as

$$R^C(0,\theta) = \beta_0 + \beta_1\left[\frac{1-\exp(-\theta/\tau_1)}{\theta/\tau_1}\right] + \beta_2\left[\frac{1-\exp(-\theta/\tau_1)}{\theta/\tau_1} - \exp(-\theta/\tau_1)\right]$$

a functional form that was later extended by Svensson as

$$R^C(0,\theta) = \beta_0 + \beta_1\left[\frac{1-\exp(-\theta/\tau_1)}{\theta/\tau_1}\right] + \beta_2\left[\frac{1-\exp(-\theta/\tau_1)}{\theta/\tau_1} - \exp(-\theta/\tau_1)\right]$$
$$+\beta_3\left[\frac{1-\exp(-\theta/\tau_2)}{\theta/\tau_2} - \exp(-\theta/\tau_2)\right]$$

where

$R^C(0, \theta)$ = continuously compounded zero-coupon rate at time zero with maturity θ

β_0 = limit of $R^C(0, \theta)$ as θ goes to infinity (In practice, β_0 should be regarded as a long-term interest-rate.)

β_1 = limit of $R^C(0, \theta) - \beta_0$ as θ goes to 0 (In practice, β_1 should be regarded as the short- to long-term spread.)

β_2, β_3 = curvature parameters

τ_1 and τ_2 are scale parameters that measure the rate at which the short- and medium-term components decay to zero.

11. John C. Cox, Jonathan E. Ingersoll, and Stephen A. Ross, "A Theory of the Term Structure of Interest Rates," *Econometrica* (March 1985), pp. 385–407.
12. For details about these models, see Martellini and Priaulet, *Fixed Income Securities: Dynamic Methods for Interest Rate Risk Pricing and Hedging*.

As shown by Svensson, the extended form is a more flexible model for yield-curve estimation, in particular in the short-term end of the curve, because it allows for more complex shapes such as U-shaped and hump-shaped curves. The parameters β_0, β_1, β_2, and β_3 typically are estimated on a daily basis by using an ordinary least squares (OLS) optimization program, which consists, for a basket of bonds, of minimizing the sum of the squared spread between the market price and the theoretical price of the bond as obtained with the model.[13]

We can see that the evolution of the zero-coupon rate $R^C(0,\theta)$ is entirely driven by the evolution of the beta parameters, the scale parameters being fixed.

In an attempt to hedge a bond, for example, one should design a global portfolio with the bond and hedging instrument so that the portfolio achieves a neutral sensitivity to each of the beta parameters. Before the method can be implemented, one therefore needs to compute the sensitivities of any arbitrary portfolio of bonds to each of the beta parameters.

Consider a bond that delivers principal or coupon and principal payments denoted by F_i at dates θ_i, for $i = 1, \ldots, m$. Its price P_0 at date $t = 0$ is given by the following formula:

$$P_0 = \sum_{i=1}^{m} F_i e^{-\theta_i R^C(0,\theta_i)}$$

In the Nelson and Siegel and Svensson models, we can calculate at date $t = 0$ the \$durations $D_i = \partial P_0/\partial \beta_i$ for $i = 0, 1, 2, 3$ of the bond P to the parameters β_0, β_1, β_2, and β_3. They are given by the following formulas:[14,15]

$$\begin{cases} D_0 = -\sum_i \theta_i F_i e^{-\theta_i R^C(0,\theta_i)} \\ D_1 = -\sum_i \theta_i \left[\dfrac{1-\exp(-\theta_i/\tau_1)}{\theta_i/\tau_1}\right] F_i e^{-\theta_i R^C(0,\theta_i)} \\ D_2 = -\sum_i \theta_i \left[\dfrac{1-\exp(-\theta_i/\tau_1)}{\theta_i/\tau_1} - \exp(-\theta_i/\tau_1)\right] F_i e^{-\theta_i R^C(0,\theta_i)} \\ D_3 = -\sum_i \theta_i \left[\dfrac{1-\exp(-\theta_i/\tau_2)}{\theta_i/\tau_2} - \exp(-\theta_i/\tau_2)\right] F_i e^{-\theta_i R^C(0,\theta_i)} \end{cases} \tag{48–10}$$

13. For more details, see Martellini, Priaulet, and Priaulet, *Fixed Income Securities: Valuation, Risk Management and Portfolio Strategies*.
14. Of course, \$duration D_3 is only obtained in the Svensson model.
15. An example of calculation of the level, slope, and curvature \$durations is given in Martellini, Priaulet, and Priaulet, *Fixed Income Securities: Valuation, Risk Management and Portfolio Strategies*. See also Andrea J. Heuson, Thomas F. Gosnell, Jr., and W. Brian Barrett, "Yield-Curve Shifts and the Selection of Immunization Strategies," *Journal of Fixed Income* (September 1995), pp. 53–64; and Ram Willner, "A New Tool for Portfolio Managers: Level, Slope and Curvature Durations," *Journal of Fixed Income* (June 1996), pp. 48–59.

Hedging Method

The next step consists of creating a global portfolio that would be unaffected by (small) changes of parameters β_0, β_1, β_2, and β_3. This portfolio will be made of

- The bond portfolio to be hedged, whose price and face value are denoted by P and N_P
- Four hedging instruments, whose prices and face values are denoted by G_i and N_{Gi}, for $i = 1, 2, 3$, and 4

We therefore look for the quantities q_0, q_1, q_2, and q_3 to invest, respectively, in the four hedging instruments G_0, G_1, G_2, and G_3 so as to satisfy the following linear system:

$$\begin{cases} q_1 N_{G_1} \dfrac{\partial G_1}{\partial \beta_0} + q_2 N_{G_2} \dfrac{\partial G_2}{\partial \beta_0} + q_3 N_{G_3} \dfrac{\partial G_3}{\partial \beta_0} + q_4 N_{G_4} \dfrac{\partial G_4}{\partial \beta_0} = -N_P D_0 \\ q_1 N_{G_1} \dfrac{\partial G_1}{\partial \beta_1} + q_2 N_{G_2} \dfrac{\partial G_2}{\partial \beta_1} + q_3 N_{G_3} \dfrac{\partial G_3}{\partial \beta_1} + q_4 N_{G_4} \dfrac{\partial G_4}{\partial \beta_1} = -N_P D_1 \\ q_1 N_{G_1} \dfrac{\partial G_1}{\partial \beta_2} + q_2 N_{G_2} \dfrac{\partial G_2}{\partial \beta_2} + q_3 N_{G_3} \dfrac{\partial G_3}{\partial \beta_2} + q_4 N_{G_4} \dfrac{\partial G_4}{\partial \beta_2} = -N_P D_2 \\ q_1 N_{G_1} \dfrac{\partial G_1}{\partial \beta_3} + q_2 N_{G_2} \dfrac{\partial G_2}{\partial \beta_3} + q_3 N_{G_3} \dfrac{\partial G_3}{\partial \beta_3} + q_4 N_{G_4} \dfrac{\partial G_4}{\partial \beta_3} = -N_P D_3 \end{cases} \tag{48–11}$$

In the Nelson and Siegel model, we only have three hedging instruments because there are only three parameters.

COMPARATIVE ANALYSIS OF VARIOUS HEDGING TECHNIQUES

We now analyze the hedging performance of three methods in the context of a specific bond portfolio. The methods we consider in this horse race are the duration hedge, the duration/convexity hedge, and the Nelson-Siegel $durations hedge.

Let us assume that at the initial date $t = 0$ the continuously compounded zero-coupon yield-curve is described by the following set of parameters of the Nelson and Siegel model[16]: $\beta_0 = 8\%$, $\beta_1 = -3\%$, $\beta_2 = -1\%$, and $\tau = 3$.

This corresponds to a standard upward-sloping yield-curve. We consider a bond portfolio whose features are summarized in Exhibit 48–1. The price is

16. Note that we can obtain the annualized compounded zero-coupon yield-curve by using the following equation:

$$R(t,\theta) = \exp[R^C(t,\theta)] - 1$$

where $R^C(t,\theta)$ is the continuously compounded zero-coupon rate at date t with maturity θ, and $R(t,\theta)$ is its annualized compounded equivalent.

EXHIBIT 48–1

Characteristics of the Bond Portfolio to Be Hedged

Price	YTM	$duration	$convexity	Level	Slope	Curvature
972.376	7.169%	–5,709.59	79,662.17	–6,118.91	–1,820.02	–1,243.28

expressed in percentage of the face value, which is equal to $100 million. We compute the yield-to-maturity (YTM), the $duration, the $convexity, and the level, slope, and curvature $durations of the bond portfolio, as given by Eq. (48–10).

To hedge the bond portfolio, we use three-plain vanilla six-month LIBOR swaps whose features are summarized in Exhibit 48–2. $duration, $convexity, level, slope, and curvature are those of the fixed-coupon bond contained in the swap. The principal amount of the swaps is $1 million. They all have an initial price of zero.

We consider that the bond portfolio and the swap instruments present the same default risk, so we are not concerned with this additional source of uncertainty, and we can use the same yield-curve to price them. This curve is the one described earlier with the Nelson and Siegel parameters.

To measure the performance of the three hedging methods, we assume 10 different possible changes in the yield-curve. These 10 scenarios are obtained by assuming the following changes in the beta parameters in the Nelson and Siegel model:

- Small parallel shifts with $\beta_0 = +0.1\%$ and $\beta_0 = -0.1\%$
- Large parallel shifts with $\beta_0 = +1\%$ and $\beta_0 = -1\%$
- Decrease and increase of the short- to long-term spread with $\beta_1 = +1\%$ and $\beta_1 = -1\%$
- Curvature moves with $\beta_2 = +0.6\%$ and $\beta_2 = -0.6\%$
- Flattening and steepening moves of the yield-curve with ($\beta_0 = -0.4\%$, $\beta_1 = +1.2\%$) and ($\beta_0 = +0.4\%$, $\beta_1 = -1.2\%$)

EXHIBIT 48–2

Characteristics of the Swap Instruments

Maturity	Swap Rate	$duration	$convexity	Level	Slope	Curvature
2 years	5.7451%	–184.00	517.09	–194.55	–142.66	–41.66

and Siegel $durations hedge is performed with the three swaps using Eq. (48–11), leading us to enter 407 2-year maturity payer swaps, to enter 219 7-year maturity receiver swaps, and to enter 696 15-year maturity payer swaps. Results are given in Exhibit 48–6, where we display the change in value of the global portfolio (which aggregates the change in value on the bond portfolio and the hedging

EXHIBIT 48–6

Hedging Errors in Dollars of the Three Different Methods: Duration, Duration/Convexity, and Nelson and Siegel $durations

Yield-Curve Scenario	No Hedge	Duration	Duration/ Convexity	Nelson-Siegel $durations
$\beta_0 = +0.1\%$	–6,076,494	–25,627	–97,826	8,573
$\beta_0 = -0.1\%$	6,161,872	71,692	97,435	2,013
$\beta_0 = +1\%$	–57,176,627	1,605,853	–1,050,770	475,891
$\beta_0 = -1\%$	65,743,922	3,028,609	1,026,043	599,622
$\beta_1 = +1\%$	–17,982,901	7,103,063	–4,934,261	15,557
$\beta_1 = -1\%$	18,421,236	–7,311,245	5,001,463	–4,959
$\beta_2 = +0.6\%$	–7,410,125	2,972,451	–400,339	1,131
$\beta_2 = -0.6\%$	7,509,714	–2,991,594	381,400	–9,038
$\beta_0 = +0.4\%$, $\beta_1 = -1.2\%$	–2,438,405	–8,665,316	5,661,669	90,991
$\beta_0 = -0.4\%$, $\beta_1 = +1.2\%$	2,839,537	9,024,298	–5,474,877	94,636

instruments), assuming that the yield-curve scenario occurs instantaneously. This change in value can be regarded as the hedging error for the strategy. It would be exactly zero for a perfect hedge.

The value of the bond portfolio is equal to $972,375,756.[17] With no hedge, we see clearly that the loss in portfolio value can be significant in all adverse scenarios.

As expected, duration hedging appears to be effective only for small parallel shifts of the yield-curve. The hedging error is positive for large parallel shifts because of the positive convexity of the portfolio. For nonparallel shifts, the loss incurred by the global portfolio can be very significant. For example, the portfolio value drops by $7,311,245 in the pure-slope scenario when $\beta_1 = -1\%$ and $8,665,316 in the steepening scenario. As also expected, duration/convexity hedging is better than duration hedging when large parallel shifts occur. On the other hand, it appears to be ineffective for all other scenarios, even if the hedging errors are still better (smaller) than those obtained with duration hedging. Finally, we see that the Nelson and Siegel $durations hedging scheme is a very reliable method for all kinds of yield-curve scenarios. In all cases, the hedging error appears to be negligible when compared with the initial value of the bond portfolio.

KEY POINTS

- A decline (rise) in interest rates will cause a rise (decline) in bond prices.
- Just as the risk on a stock portfolio is usually proxied by its beta, which is a measure of the stock sensitivity to market movements, bond price risk is most often measured in terms of the bond interest-rate sensitivity, or duration. This is a convenient one-dimensional measure of the bond's sensitivity to interest-rate movements.
- Duration provides a portfolio manager with a convenient hedging strategy: to offset the risks related to a small change in the level of the yield-curve, a portfolio manager should optimally invest in a hedging asset a proportion equal to the opposite of the ratio of the (dollar) duration of the bond portfolio to be hedged by the (dollar) duration of the hedging instrument.
- Duration hedging is convenient because it is very simple. However, it is based on the following very restrictive assumptions: (1) changes in the yield curve will be small, and (2) the yield curve is only affected by parallel shifts.
- An empirical analysis of major government bond markets suggests, however, that large variations can affect the yield-to-maturity curve and that three main factors (level, slope, and curvature) have been found to

17. Opposite results in terms of hedging errors would be obtained if the investor were to short the bond portfolio.

drive the dynamics of the yield-curve. This strongly suggests that duration hedging is inefficient in many circumstances.

- By relaxing the two assumptions for duration hedging, better methodologies for hedging can be developed.
- Relaxing the assumption of a small change in the yield-curve can be performed though the introduction of a convexity adjustment in the procedure. Convexity is a measure of the sensitivity of dollar duration with respect to yield changes.
- Accounting for general, nonparallel deformations of the term structure is not easy because it increases the dimensionality of the problem.
- Because it is never easy to hedge the risk associated with too many sources of uncertainty, it is always desirable to try to reduce the number of risk factors and identify a limited number of common factors. This can be done in a systematic way by using an appropriate statistical analysis of the yield-curve dynamics. Alternatively, one may choose to use a model for the discount-rate function.

BOND PORTFOLIO MANAGEMENT

This page intentionally left blank

CHAPTER
FORTY-NINE

INTRODUCTION TO BOND PORTFOLIO MANAGEMENT

KENNETH E. VOLPERT, CFA
Head of the Taxable Bond Group
The Vanguard Group, Inc.

Traditional bond management can be likened to a sailing regatta. The index is the lead boat, since it doesn't have to contend with expenses and transaction costs, and all managers (including index fund managers) are the other boats, trying to make up the distance and pass the index boat—or at least keep pace with it. Strategies that may be used to make up the difference and pass the index lead boat comprise a wide spectrum of styles and approaches. Exhibit 49–1 displays the major elements of these approaches.

In this chapter, we'll examine this spectrum, investigating the pros and cons of matching—and mismatching—bond indexes, and comparing ways of constructing bond portfolios. We'll look closely at the factors to consider when matching a bond index's risk factors, as well as the methods that may provide an edge over an index.

OVERVIEW OF TRADITIONAL BOND MANAGEMENT

Although bond portfolio management can be complicated, choosing an investment approach starts with a fairly simple question: How much risk would you like to take?

Pure Bond Index Matching

Pure bond indexing offers the lowest risk (and lowest expected return) approach to bond management versus a specific benchmark. This approach essentially guarantees that returns will lag behind the index by the cost difference (expenses plus transaction costs). Pure bond index matching attempts to fully replicate the index by owning all of the bonds in the index in the same proportion as the index. In the bond market, however, this approach is difficult to accomplish and costly to implement. Many bonds in the index were issued years ago, and are illiquid. Also, many bonds were issued at a time when interest rates were significantly

EXHIBIT 49–1

Traditional Bond Management Risk Sprectrum

different from current rates. Today's bond holders may be unwilling to incur a gain or loss by selling their bonds to an index fund.

On December 31, 2010, the Barclays Capital Aggregate Bond Index contained more than 8,200 different issues, including more than 190 Treasury issues, 940 federal agency issues, 4,200 credit (corporate and non-U.S. government) issues, 120 asset-backed issues, 1,550 commercial mortgage-backed securities, and 1,200 broadly categorized mortgage issues (essentially hundreds of thousands of mortgage pools). In the Treasury market, matching an index, security by security, is feasible, although not desirable (for reasons we'll cover later). However, full replication cannot be reasonably implemented in the agency, mortgage, or corporate bond markets. Thousands of agency and corporate issues are locked away in long-term bond portfolios and must be purchased from the investors who own them—often at a large premium. For this reason, full replication of a broad bond index is inefficient, if not impossible. And, as you'll see, it's also unnecessary.

Enhanced Indexing: Matching Primary Risk Factors

This approach involves investing in a large sample of bonds so that the portfolio's risk factors match the index's risk factors. The result is a portfolio that will have higher average monthly tracking differences (standard deviation of tracking differences) than the full-replication approach. But, it can be implemented and maintained at a much lower cost. This lower cost results in *net* investment performance that is much closer to the index. Returning to the regatta analogy, the

portfolio boat stays on the same "tack" as the index boat, but "trims its sails" to run more efficiently. Staying on the same tack means that the sails are set to take the portfolio boat in the same direction as the index boat, and are exposed to the same winds and elements. By trimming the sails, the little details of the portfolio boat's sail position and shape result in better performance and more efficient execution than the index boat. The risk factors that need to be matched are duration, cash-flow distribution, sector, quality, and call exposure (more on this later). This approach is considered a form of enhanced indexing because the return is enhanced relative to the full replication indexing approach (more on this later as well).

Enhanced Indexing: Minor Risk Factor Mismatches

This approach allows for minor mismatches in the risk factors (except duration) to tilt the portfolio in favor of particular areas of relative value, such as certain sectors, credit ratings, term structure, call risk, or other factors. Because the mismatches (and impact on tracking) are very small, this is still considered enhanced indexing. These additional enhancements are essentially sail-trimming strategies.

Active Management: Larger Risk Factor Mismatches

This is a conservative approach to active management. The manager will make larger mismatches in the risk factors in an attempt to add greater value. This approach may also make small duration bets. In most cases, the management fee and transaction costs are significantly higher than for pure or enhanced indexing, yet the net investment return is usually lower. These additional costs are the reason a typical index portfolio often outperforms the average active manager in performance universes. Typically, the manager will moderately change tack to seek greater "winds" (for example, longer than benchmark duration to add value from expected lower interest rates) to overcome the strategy's higher cost. As a result, manager risk increases the likelihood that the portfolio will deviate from the market return and structure.

Active Management: Full-Blown Active

This is an aggressive active style in which large duration and sector bets are made, and significant variation from the index can occur. Above-average performance consistency is difficult to find among the managers that employ this approach. As a result, investors who choose this management style need to look deeper than recent performance to distinguish the good from the bad. This approach may involve a significant changing of course relative to the index boat, and may risk significant tracking and portfolio structure variations. Of course, the goal of this riskier strategy is to provide a return that is higher than that of the index.

OVERVIEW OF THE CORE/SATELLITE APPROACH

Although these traditional approaches are alive and well, many investment managers have moved a few steps beyond this conventional model and are building portfolios with a conservative, low-cost (often index-based) core, and satellites that may encompass a variety of active strategies. As shown in Exhibit 49–2, a core portfolio is typically managed against a broad, liquid benchmark within a tight risk budget, generally under 40 basis points ex-ante tracking standard deviation versus the benchmark. As we'll see, there are several ways to build the core and the satellite portions of such portfolios.

Risk-Factor Matching

In this strategy, the manager creates a broadly diversified portfolio that closely replicates primary index risk factors such as portfolio duration, key rate durations, sectors, quality, and callability. The ex-ante tracking error is expected to be below 20 basis points. Since this high-quality, liquid bond market is assumed to be efficiently priced, the expected opportunity to outperform the index is very limited. Therefore, the objective is to match and replicate the risks, and generate the returns, of the target benchmark at the lowest possible cost (management fee and transaction costs).

Minor Mismatching

Here, the manager is given a larger risk budget (20 to 40 basis points) to mismatch relative to a broad liquid benchmark's characteristics such as key rate durations, sector and quality weightings, and even overall portfolio duration, to a

EXHIBIT 49–2

Core/Satellite Risk Spectrum

limited extent. The expectation is that the manager will add value relative to that broad benchmark. As a result of this expected added value, the manager would also have a higher fee structure.

The Satellite Investments

The satellite portion focuses on the less-liquid sectors that have lower correlations with the broad liquid core. This manager is given a smaller pool of assets and a much larger risk budget relative to the narrow benchmark. This bigger risk budget provides an opportunity for the manager to take meaningful selection, sector, and quality risk relative to the benchmark, with the expectation of adding considerable value.

Examples of such narrow, less-liquid markets include high-yield and emerging market bonds. In the high-yield market, issuer and sector selection are the primary determinants of added value versus the benchmark. Within the emerging bond market, country selection is a driving force in adding value. In many cases, the mortgage-backed market (agency and particularly nonagency) is viewed as a satellite market because of the many structural complexities based on interest-rate volatility risk and credit risk in the nonagency market. Securities exposed to non-U.S. currencies may be considered satellites, as could inflation-protected securities.

A key requirement of the satellite component is that it acts as a diversifier and that it has a higher expected return due to its illiquidity and lower credit quality.

WHY CHOOSE INDEXING?

As we've demonstrated, indexing plays a major role in bond management. Some managers may use indexing for part of a portfolio; for other managers, it may serve as the approach for an entire portfolio. So why is indexing an effective method of bond investing? Put simply, bond indexing, which has proven its mettle over the past two decades, offers broad diversification and low costs. Low costs are vital to bond indexing because lower costs mean tighter tracking of an index. This, in turn, means that an index portfolio will provide competitive performance that is consistent with the market—or market segment—that it tracks. And it means that nonindex (that is, higher-cost) portfolios will have difficulty beating the index portfolio. Finally, indexing provides a major psychological benefit: It allows investors to focus on asset allocation—or, in the case of the core/satellite approach, on selecting the best investment managers.

Broad Diversification

Broad bond index portfolios provide excellent diversification. The Barclays Capital Aggregate Bond Index, which is designed to capture the entire U.S. investment-grade bond market, had over 8,200 issues and more than $15 trillion in market value

as of December 31, 2010. A large bond index portfolio designed to replicate this Index may have 1,000 to 3,000 or more issues, resulting in significant issuer diversification benefits. Most active portfolios have much heavier specific issuer concentrations, resulting in significant exposure to issuer event (credit) risk.

In addition, an index portfolio designed to match the Barclays Capital Aggregate Bond Index will have exposure to not only Treasury and agency sectors, but also to mortgages, industrials, electric and telephone utilities, finance, dollar-denominated non-U.S., and asset-backed sectors. Such a portfolio will also have broad exposure to the yield-curve with holdings from one year to more than 30 years to maturity. These sources of diversification result in a portfolio with lower risk for a given level of return than is available from less diversified portfolios.

Low Cost

As we've mentioned, the primary reason for an index fund's competitive performance is lower cost. This lower cost takes two forms: (1) lower management fees, and (2) lower transaction costs associated with lower portfolio turnover rates. This lower cost advantage is durable and predictable—year after year. Morningstar president Don Phillips summarizes the impact of higher costs this way: "If you pay the executive at Sara Lee more, it doesn't make the cheesecake less good. But with mutual funds (investment management), it comes directly out of the batter." It sure does!

Competitive Performance

Since index portfolios have lower management fees and lower transaction costs (resulting from significantly lower portfolio turnover), it's not surprising that they usually outperform the average active portfolio in most universes. After all, a broad index, by design, is a representation of the whole pie of investment alternatives. As a result, the sum of all active managers should equal the index in composition. Also, the sum of the investment performance of all active managers (grossed up for the higher management fees and transaction costs) should also equal the index in performance. In the mutual fund market, where the bond index expense ratio advantage is about 0.8% per year, the Barclays Capital Aggregate Bond Index (adjusted for an estimated 20 basis point expense ratio) outperformed more than 49% of its Lipper Group over three years, 60% over five years, and 71% over ten years ended December 31, 2010.

Consistent Relative Performance

Exhibit 49–3 shows the performance for the Barclays Aggregate Bond Index (adjusted for an estimated 20 basis point expense ratio) against its Lipper universe (Intermediate Investment-Grade) for calendar years starting in 1994.

EXHIBIT 49–3

Annual Performance Relative Consistency Analysis—versus Lipper Intermediate Investment-Grade

	Index Return*	Percent Outperformed
1994	–3.12	64%
1995	18.27	80%
1996	3.43	70%
1997	9.45	86%
1998	8.49	80%
1999	–1.02	68%
2000	11.43	80%
2001	8.24	82%
2002	10.06	90%
2003	3.90	42%
2004	4.34	71%
2005	2.43	84%
2006	4.33	72%
2007	6.97	90%
2008	5.24	92%
2009	5.93	9%
2010	6.54	24%

3 Years	6.90	49%
5 Years	5.80	60%
10 Years	5.84	71%

*Barclays Capital Aggregate Bond Index return-0.2%

The only years that this portfolio outperformed less than 50% of the universe were 2003, 2009, and 2010. The 2003 "underperformance" was due primarily to the poor performance of the mortgage-backed securities sector, which suffered at the hands of heavy refinancing activity. In 2009 and 2010, Lipper funds were overweighted to credit amid a significant credit rebound following the 2008 credit crisis and recession. In the other years, the portfolio outperformed between 64% and 92% of the competition in its maturity and quality categories. Over the full ten years, the average was a remarkable 71%. The primary reason for this consistent outperformance was the index portfolio's significantly lower expenses and transaction costs.

Market Performance Predictability

A properly managed broad bond index portfolio can be assured of performing in line with the market as a whole. Regardless of the market's direction, the investor can be assured the performance of a diversified broad bond index portfolio will follow along.

A Time-Tested Track Record

Bond index portfolios have been successfully managed (that is, close tracking to the benchmark) since the early 1980s—through rising and falling interest rate cycles, as well as periods when credit-spreads widened and narrowed. Through all these market changes, bond indexing has proven to provide a more-than-competitive return with low to moderate risk.

Perhaps the most significant benefit of indexing is that it enables investors to concentrate on more important decisions—namely, the proper allocation of assets. Often, time and effort are wasted in the hope of adding 20 to 40 basis points to the very efficiently priced bond portion of a portfolio, while existing misallocation of assets to stocks or international investments results in hundreds of basis points of underperformance for the entire portfolio. Indexing the core portion of the portfolio that represents the highly liquid markets helps facilitate more effective use of limited decision-making resources available to most investors. For those using a core/satellite approach, indexing provides an opportunity to focus on selecting the best managers for the satellites.

WHICH INDEX SHOULD BE USED?

Once you've decided on an indexing approach to bond management, you should focus on the next important question: Which index? A bond index is defined by a set of rules (that is, characteristics) that are then applied to all issues in the marketplace. The rules include maturity, size, sector, and quality characteristics. The issues that fit the rules are then combined, as if in a portfolio, with each issue's weight determined by its relative market value outstanding.

Generally, the broader the index, the better the benchmark. An index we've discussed, the Barclays Capital Aggregate Bond Index, is the broadest U.S. bond index. (It's essentially identical to the Citigroup Broad Investment-Grade Index and the Merrill Lynch Domestic Master Index.) As we've mentioned, on December 31, 2010 the Barclays Capital Aggregate Bond Index consisted of more than 8,200 issues, representing a market value of more than $15 trillion. The composition of the Index, illustrated in Exhibit 49–4, was 41% government (U.S. Treasury and agency) bonds, 23% credit-related (corporate and non-U.S. government) bonds, 3% asset-backed bonds and commercial mortgage-backed bonds, and 33% mortgage-backed securities. The option-adjusted duration—a number that reflects the possibility of bonds being called by the issuer—was in the intermediate duration range, at 5.0, with an average maturity of 7.1 years, making it the broadest domestic intermediate investment-grade index available. Sub-indices of the Barclays Capital Aggregate Bond Index can be created to capture that result in different risk/return profiles. For example, a credit index may appeal to those who seek higher yields from the spread sectors, or a 1-to-5-year government/credit index would better serve those who are seeking a short-duration portfolio.

EXHIBIT 49–4

Barclays Capital Aggregate Bond Index Composition (as of 12/31/2010)

Sector	Percent of Market Value
Government	41
ABS/CMBS	3
MBS	33
Credit Related	23

Maturity	Percent of Market Value
MBS	33
ABS/CMBS	3
1-5 Gov/Credit	34
5-10 Gov/Credit	19
10+ Gov/Credit	11

An important part of choosing an index is understanding the risks that are involved in the bond market's various segments. Chief among these risks are market value risk and income risk, although the degree to which they apply to a given part of the bond market can vary widely.

Market Value Risk

Generally, the longer a bond portfolio's maturity, the higher is its yield. (This assumes a normally sloped yield-curve.) The total return of a bond is made up of the coupon (or income) component and the principal (or price change) component. Since the yield-curve, which impacts the principal component of total return, is likely to shift, the longer-term bond portfolio will not necessarily have a higher total return. Exhibit 49–5 shows the one-year total return of different maturity securities in both high-rate and low-rate environments. Clearly, as the maturity or duration of the portfolio lengthens, market value risk rises. In addition, the lower the interest-rate environment, the greater the market value risk, especially for the intermediate-term and long-term portfolios. This is the result of two factors: the portfolio's duration increases as interest rates decrease, and the portfolio's lower yield-to-maturity provides less of a cushion to offset principal losses. Therefore, for investors who are risk-averse in terms of their principal, the short-term or intermediate-term index may be more appropriate than the long-term index.

Income Risk

Many investors invest for income. They spend only the income that their investment distributes, and they avoid dipping into their principal. Foundations and retirees invest for a stable—and hopefully growing—income stream that they can

EXHIBIT 49–5

Market Value Risk: One-Year Rates of Return in High and Low Interest Rate Environments

High-Interest-Rate Environment				*One-Year Return (Income + Price Return)*	
Coupon	**Maturity**	**Price**	**Duration**	**Rates Rise 1%**	**Rates Fall 1%**
12%	3 Year	100	2.5	9.6%	14.5%
12%	7 Year	100	4.6	7.5%	16.8%
12%	20 Year	100	7.5	4.9%	20.0%
Low-Interest-Rate Environment				*One-Year Return (Income + Price Return)*	
Coupon	**Maturity**	**Price**	**Duration**	**Rates Rise 1%**	**Rates Fall 1%**
4%	3 Year	100	2.8	2.1%	5.9%
4%	7 Year	100	6.2	–1.1%	9.4%
4%	20 Year	100	14.3	–8.2%	18.4%

depend on for current and future consumption. Exhibit 49–6 shows the income stream from a hypothetical $10,000 investment in short-term (three-year), intermediate-term (seven-year), and long-term (20-year) mutual funds during the 25 years of declining interest rates from 1980 to the mid-2000s, assuming equivalent growth rates for the portfolios. It's obvious that if stability and durability of

EXHIBIT 49–6

Income Risk

income are the primary concerns, the long-term portfolio is the least risky, and the short-term portfolio the most risky.

Liability Framework Risk

Pension funds and financial institutions invest to finance future liabilities. Long-term liabilities require investments in long-term assets to minimize risk, resulting in both a portfolio and a liability stream that are equally sensitive to interest-rate changes. A portfolio that invests in short-term bonds may look less risky on an absolute-return basis, but it is actually much riskier when the portfolio market value is compared to the present value of the pension liability. (The difference is the surplus or deficit.) This is because of the short-term portfolio's mismatch with its long-term liabilities. The surplus risk will be minimized on a fully funded plan when the duration of the portfolio is matched (or immunized) to the duration of the liability.

Exhibit 49–7 contains a summary comparison showing that the investment with the lowest market value risk has the highest income or liability risk. Likewise, the investment with the highest market value risk has the lowest income or liability risk. Clearly, the risk framework chosen depends on whether the investment objective is principal preservation or income durability.

PRIMARY BOND INDEXING RISK FACTORS

As effective as indexing is as a bond management tool, it doesn't eliminate the risks of bond investing by any means. Successful indexing requires matching the primary risk factors of the benchmark index in a credit-diversified portfolio. This doesn't mean an index manager must fully replicate an index. Rather, it means

EXHIBIT 49–7

Bond Market Risk Summary

NAV Type	Market-Value Risk	Income or Liability Risk	Average Maturity	Current Duration	Portfolios
Stable-dollar NAV	Lowest	Highest	30–90 Days	0.1	Money market portfolios
Variable NAV	Low	High	2–4 Years	2.5	Short-term portfolios
	Medium	Medium	7–10 Years	5.0	Intermediate-term portfolios
	High	Low	15–25 Years	10.0	Long-term portfolios

EXHIBIT 49–8

Primary Bond Index Matching Factors

	Government	Corporate	MBS
Modified adjusted duration	x	x	
Present value of cash-flows	x	x	
Percent in sector and quality		x	
Duration contribution of sector		x	
Sector/coupon/maturity cell weights		x	x
Issuer exposure control		x	

that the manager must understand the risk factors and how they're measured. Exhibit 49–8 lists the primary risk factors that apply to the government, corporate, and mortgage sectors; the following paragraphs explain each primary risk factor.

Portfolio Modified Adjusted Duration

The modified adjusted duration (or option-adjusted modified duration) is a simple, single measure of the portfolio's interest-rate risk (see Exhibit 49–9). It's a great place to start, but is entirely too rough of a measure to adequately track an index. Duration is the average time to receipt of the present value of the bond cash-flows. The portfolio duration will give the manager a rough approximation of the price change observed if interest rates rise or fall (in a parallel fashion) immediately by 1%. If rates rise by 1%, a five-year duration portfolio will experience a 5% decline in value [(+1% yield change) × (portfolio duration of 5 years) × (−1)]. If the yield-curve does not move in a parallel fashion, the duration is of limited value. For obvious reasons, it's important to match the duration of the portfolio to the duration of the benchmark index.

Key Rate Durations

A more accurate way to capture yield-curve risk is by matching the key rate durations (known as KRDs) of the index. Yield-curve changes are composed of parallel shifts, curve twists (for example, short rates down, intermediate rates unchanged, long rates up), and curve butterfly movements (for example, short and long rates down, intermediate rates up). By breaking down the index (and portfolio) into a stream of future payments and discounting each payment to the present value and summing these values, one calculates the index (and portfolio) market value. By matching the percent of the portfolio's present value that comes due at certain intervals in time (that is, KRDs) with that of the benchmark index, the portfolio will be largely protected from tracking errors (versus the benchmark) associated

EXHIBIT 49–9

Key Rate Duration Distribution Analysis for Barclays Capital Aggregate Bond Index (as of 12/31/2010)

KRD	Contribution	Percent of Duration
6 month	0.13	2.7%
2 year	0.68	14.0%
5 year	1.36	28.3%
10 year	1.33	27.5%
20 year	0.68	14.0%
30 year	0.65	13.4%
Total	4.82	100.0%

Generated using BlackRock Solutions' Aladdin Risk Management model.

with yield-curve changes. Since the portfolio duration is equal to the benchmark index duration, this method will guard against parallel changes in yield. Since all points in time (KRDs) are closely matched in percent, any local term structure movements (non-parallel changes) will not affect tracking because these yield change risks are essentially immunized. For callable securities, the cash-flows need to be distributed to the KRDs in accordance with the probability of call. A 10-year bond that is highly likely to be called in three years should have cash-flows that are allocated primarily to the three-year KRD.

Percent in Sector and Quality

The yield of the index is largely replicated by matching the percentage weight in the various sectors and qualities, assuming that the replicating portfolio fully accounts for all maturity categories. Matching duration contribution of sectors and qualities, without matching the portfolio percentage weight exposed to the sectors and qualities, may expose the portfolio to significant tracking risk during periods of extreme duress. This is due to the default risk that can reduce the value of all of an issuer's bonds by a given magnitude, regardless of the maturity.

Duration Contribution of Sector

An effective way of protecting a portfolio from tracking differences associated with changes in sector spreads (industry risk) is to match the amount of the index duration that comes from the various sectors (see Exhibit 49–10). (This can be done without excessively constraining the process, subject to managing the market weights, as we've described earlier.) If this can be accomplished, a given change in sector spreads will have an equal impact on the portfolio and the index.

EXHIBIT 49–10

Sector and Quality Distribution Analysis for Barclays Capital Bond Index (as of 12/31/2010)

Sector	MV	Duration	Duration Contribution	Percent of Duration
Treasury	33.7	5.4	1.81	37.6
Agency	7.5	3.1	0.23	4.8
Industrial	9.8	7.1	0.70	14.5
Utility	2.1	8.1	0.17	3.5
Finance	6.6	5.5	0.36	7.5
Sovereign	1.1	7.3	0.08	1.7
Non-U.S. Corporate	2.4	6.7	0.16	3.3
Supranational	1.2	3.3	0.04	0.8
GNMA	6.5	4.0	0.26	5.4
FNMA	15.4	3.4	0.53	11.0
FHLMC	10.5	3.4	0.36	7.5
Asset-Backed	0.3	3.6	0.01	0.2
CMBS	2.9	3.8	0.11	2.3
Total	100.0		4.82	100.0

Quality	MV	Duration	Duration Contribution	Percent of Duration
AAA	77.9	4.3	3.36	69.7
AA	4.4	6.1	0.27	5.5
A	9.7	6.5	0.63	13.2
BBB	8.0	6.9	0.56	11.6
Total	100.0		4.82	100.0

Duration Contribution of Quality

Similarly, the most effective way to protect a portfolio from tracking differences related to changes in quality spreads (leverage/economic risk) is to match the amount of the index duration that comes from the various quality categories. This is particularly important in the lower-rated categories, which are characterized by larger spread changes.

Sector/Coupon/Maturity Cell Weights

The call exposure of an index is difficult to replicate. By itself, the convexity value (convexity measures how a bond's duration changes as yield levels change) is inadequate since it measures expected changes in duration over a small change in yield levels. In addition, the change in convexity can be very different as yield levels change. Managers who attempt to match only the index convexity value often find

themselves having to buy or sell highly illiquid callable securities to stay matched and, in the process, generating excessive transaction costs. A better method of matching the call exposure is to match the sector, coupon, and maturity weights of the callable sectors. By matching these weights, the convexity of the index should be matched. In addition, as rates change, the changes in call exposure (convexity) of the portfolio will be matched to the index, requiring little or no rebalancing.

In the mortgage market, call (prepayment) risk is significant. The volatility in the option-adjusted duration of the Barclays Capital Mortgage Index, which measures the extent of the call exposure of the mortgage market, between 1991 and 2010 is shown in Exhibit 49–11. The graph also shows, over the same 20-year period, the Mortgage Bankers Refinancing Index (inverted), which measures the extent of mortgage refinancing occurring in the market. Clearly, the greater the refinancing activity, the shorter the index duration due to the greater likelihood that the higher coupons (issues priced above par) will be refinanced with lower coupon securities. For this reason, matching the coupon distribution of the mortgage index is critical. The best risk management is accomplished by matching the index weights in a multidimensional matrix of the maturity (balloon, 15-year, 30-year), sector (FNMA, FHLMC, GNMA), coupon (0.5% increments), and seasoning (new, moderate, and seasoned). This level of detail is easily accomplished in a large portfolio (more than $1 billion in assets), but more difficult in smaller portfolios.

The FNMA and FHLMC's government-sponsored enterprises (GSE) disclosures of additional pool detail, such as FICO scores and average loan balances, result in further division of mortgage pricing of specified pools from "to be announced" (TBA) mortgage pricing.

EXHIBIT 49–11

Mortgage Call Exposure Analysis

Issuer Exposure

If the major risk factors described above are matched but with a limited number of issuers, one significant risk remains, but it can still be diversified away. Event risk—a risk widely watched during periods of significant corporate leveraging events (leveraged buyouts, LBOs) or during periods of significant economic stress—needs to be measured and controlled. Issuer exposure, like exposure to sector and quality, must first be measured in percentage terms versus the issuer weight in the index, because periods of serious economic distress can cause bond prices, regardless of maturity, to drop precipitously. However, setting market value limits without regard to issuer duration risk and issuer index weights is not adequate. Spreads widen immediately after a negative credit event. Therefore, an additional measure of the issuer event risk impact on a portfolio is the impact on portfolio market value of that spread widening. This can be measured by calculating how much of the portfolio duration (duration contribution) comes from the holdings in each issuer. This calculation should also be figured for the index. The basis-point impact on tracking of a spread-widening event will be the spread change (of the issuer) multiplied by the difference in duration contribution (portfolio − index) multiplied by (−1). Exhibit 49–12 provides an example of this analysis. Issuer XXX Corp has an equal percent weight to the index, but its duration contribution is 0.16 greater. If an event occurred that would widen XXX Corp spreads by 100 basis points, the portfolio would suffer an unfavorable tracking difference of 16 basis points versus the index (100 basis point spread change x 0.16 duration contribution overweight × −1). If the same 100-basis-point widening were to occur to XYZ Corp bonds, the tracking difference would be a favorable 8 basis points even though the percent weight is matched to the index. For effective index fund management, duration contribution exposure limits (versus the index) need to be set at the issuer level.

ENHANCING BOND INDEXING

In sailing, speed comes from paying close attention to the details, not simply from watching the wind. And in bond management, the return versus the benchmark is a function of more than just interest-rate maneuvering. Portfolio managers can trim their portfolio sails to compete more efficiently in the investment management race. Some trimming strategies include lower costs, issue selection, yield-curve positioning, sector and quality positioning, and call-exposure positioning.

Why Enhancements Are Necessary

Since the index does not incur expenses or transaction costs, enhancements are needed just to provide a net return equal to the index. Operating expenses provide a significant headwind, but transaction costs associated with portfolio growth are a major contributor to return shortfalls.

Exhibit 49–13 shows the transaction costs and resulting tracking error associated with single contribution growth and compares it with multiple contribution

EXHIBIT 49–12

Issuer Exposure Comparison (Percent of Market Value versus Duration Contribution)

	Portfolio			*Index*			*Portfolio – Index*	
	Percent of Market Value	Duration	Duration Contribution	Percent of Market Value	Duration	Duration Contribution	Percent Difference	Contribution Difference
XXX Corp	4%	8	0.32	4%	4	0.16	0%	0.16
ZZZ Corp	4%	4	0.16	4%	4	0.16	0%	0.00
XYZ Corp	4%	2	0.08	4%	4	0%	0%	–0.08

EXHIBIT 49–13

Single Contribution versus Multiple Contributions

	Portfolio Market Value	Contribution	Trans. Cost ($ at 18 bp)	Now Portfolio Value	Tracking Error from Trans Cost (bp)	(bp)
Single contribution	$ —	$250,000,000	$450,000	$249,550,000	18.0	18.0
Multiple contributions	$ —	$ 50,000,000	$ 90,000	$ 49,910,000	18.0	18.0
	$ 49,910,000	$ 50,000,000	$ 90,000	$ 99,820,000	9.0	27.0
	$ 99,820,000	$ 50,000,000	$ 90,000	$149,730,000	6.0	33.1
	$149,730,000	$ 50,000,000	$ 90,000	$199,640,000	4.5	37.6
	$199,640,000	$ 50,000,000	$ 90,000	$249,550,000	3.6	41.2
		$250,000,000	$450,000			

EXHIBIT 49–14

Why Enhancements Are Necessary: Return Impact of Transaction Costs over One Year

growth. In this example, the single contribution portfolio has a tracking error of 18 basis points associated with investing net cash-flow. In the multiple-contribution portfolio, the tracking error is significantly higher, at 41 basis points, even though the amount of transaction costs ($450,000) is identical. Therefore, portfolios with high growth rates will suffer additional negative tracking errors. So, enhancements are necessary simply to stay equal to a no-growth or slow-growth portfolio. Exhibit 49–14 shows, in graphical form, the cumulative adverse tracking impact resulting from portfolio growth for Treasury, government/corporate, and corporate portfolios. The greater the growth rate—and/or the less liquid the market—the greater the adverse impact on tracking error.

Lower-Cost Enhancements

One of the simplest, yet most overlooked, forms of enhancement is keeping costs low. Expenses/management fees and transaction costs have a significant impact on portfolio performance.

Active managers work hard—and usually unsuccessfully—to add an incremental 25 to 50 basis points per year to portfolio gross returns. Yet in the mutual fund arena, the average bond fund expense ratio is 50 to 80 basis points greater than that of the lowest-cost index portfolio. As a result, net returns of the high-expense-ratio funds are significantly lower. Even in the indexing arena, expenses vary by large margins. An investor can enhance returns simply by shopping around for the index fund with the lowest expenses, provided the net return is competitive with other index funds. For a plan sponsor with external index fund

managers, having the current fund manager and one or two other reputable index fund managers rebid the business every few years will help ensure expenses are as low as possible.

Transaction costs are the other major cost factor. Since bond index funds have low annual turnover (about 40%) versus active portfolios (generally greater than 100%), transaction costs are significantly lower for index portfolios. In addition, electronic trading platforms, which enable managers to increase price competition among dealers, further reduce the transaction-cost impact. It's imperative to include a number of brokers in the bidding process. For rapidly growing portfolios, where most of the transactions are offerings, an effective competitive trading process is essential. An efficient system of comparing the relative value of real-time offerings of target issuers and issues from many different brokers will yield significant transaction cost savings and, as a result, further enhance returns.

Issue Selection Enhancements

For U.S. Treasury securities, the primary tool for selecting cheap bonds is comparing actual bond prices to the theoretical "fitted" price. The theoretical curve minimizes the pricing errors of all Treasury issues in the market, subject to various curve-smoothing rules. Each actual bond's yield is then compared to the bond's fitted yield, which is calculated using the theoretical curve. Bonds yielding more than the fitted yield are cheap; those yielding less are rich. Also useful is an analysis of the recent history of the bond yield versus the fitted yield. This analysis will indicate whether a cheap bond has been getting cheaper or richer.

Corporate issue selection enhancements come primarily from staying clear of deteriorating credits and owning improving credits. The greater the manager's confidence in the ability of the firm's credit analyst to add value via issuer selection, the larger the maximum issuer exposure limit. (See "Primary Bond Indexing Risk Factors—Issuer Exposure" in this chapter.) If the manager does not believe the firm's credit analysts can add value through issuer selection, the diversification among issuers must be greater.

Yield-Curve Enhancements

Various maturities along the term structure are consistently overvalued or undervalued. For example, the 10-year and 30-year Treasury regions tend to be consistently overvalued, due to the liquidity preference of those regions. Strategies that overweight the undervalued maturities and underweight the overvalued maturities, while keeping the same general term structure exposure, have tended to outperform the index. This is similar to looking for the maturities that have the more favorable "rolldown" characteristics—that is, the near-term passage of time may result in the bond rolling down the yield-curve. As a result, the security trades at a lower yield and has more opportunity for price appreciation. Cheap

parts of the curve tend to have favorable roll down, while rich parts of the curve (for example, the 30-year area) tend to have little or no roll-down opportunities.

Sector/Quality Enhancements

Sector and quality enhancements take two primary forms: (1) ongoing yield tilt toward short duration corporates, and (2) periodic, minor overweighting or underweighting of sectors or qualities.

The yield-tilt enhancement (also called "corporate substitution") strategy recognizes that the best yield spread per unit of duration risk is available in short-term (under 5-year) corporates. A strategy that underweights 1–5-year government bonds and overweights 1–5-year corporates has tended to increase the yield of the portfolio with a less-than-commensurate increase in risk—except during periods of severe economic stress. Exhibit 49–15 shows the rolling 12-month return difference between the Barclays Capital 1–5 Year Corporate Index and the Barclays Capital 1–5 Year Treasury Index.

The persistent return enhancement is obvious for all periods over the last 15 years except for the brief spread-widening periods of 1990, 1998, 2000, and 2002, and a very significant widening in 2008. An economic downturn that results in significant downgrades from investment-grade to high-yield or leads to significant defaults would prove disastrous to this strategy.

EXHIBIT 49–15

Barclays 1–5 Year Corporate versus Barclays 1–5 Year Treasury Index: Rolling 12-Month Total Return Difference

EXHIBIT 49–16

Break-Even Spread Widening Analysis: Corporates versus Treasuries (Assumes One-year Holding Period)

Maturity	Wide Spreads	Break-Even Add'l Widening	Moderate Spreads	Break-Even Add'l Widening	Narrow Spreads	Break-Even Add'l Widening
2 years	120	155	80	105	40	55
3 years	130	81	90	59	50	37
5 years	140	46	100	34	60	23
10 years	150	25	110	19	70	13
30 years	200	18	150	14	100	10

The strategy has proven effective primarily because the yield advantage of a broadly diversified portfolio of short-term corporates requires a significant corporate spread-widening move over a one-year period for short-term corporates to perform as poorly as short-term Treasuries. Exhibit 49–16 shows the spread increases that would be required to break-even with equal-risk Treasury securities over a one-year holding period. With the passage of time, the duration of corporate bonds shortens, and the yield spread over comparable Treasury securities generally narrows. These risk- reducing and return-enhancing forces, when combined with the yield-spread advantage, provide compelling reasons to overweight short corporates using a broadly diversified credit portfolio. Even at narrow spreads, significant protection is available in maturities under five years. Over the next year, a diversified two-year corporate portfolio with a yield spread of 40 basis points can widen by another 55 basis points versus a comparable duration Treasury portfolio security before it performs as poorly as the comparable Treasury portfolio. Clearly, as the maturities increase, the spread-widening protection decreases.

The risks involved in the strategy are recessionary spread widening risk and issuer default risk. The recessionary spread widening risk tends to be short-lived and quickly overcome by the increased yield advantage of the strategy. The issuer default risk can be minimized by broad issuer diversification (50 or more issuers), by limiting the strategy to A-rated and higher issuers, and by experienced credit analyst oversight.

The periodic overweighting or underweighting of sectors and qualities is a scaled-back version of active "sector rotation." This can be implemented on a cost-effective basis by allowing new cash-flow (net new portfolio growth) to facilitate the mismatching. For example, if spreads are narrow going into the fourth quarter and the manager expects some widening, new money may be invested in Treasury securities to a moderate degree, resulting in a modest reduction in the corporate exposure versus the index. Once the corporate spread widening materializes, Treasury securities (with low transaction costs) can be sold and

corporates overweighted. Expected first quarter asset growth will eventually bring the corporate weighting back in line with the index. A strategy of outright selling of corporates to buy Treasury securities is always difficult to justify because of the higher corporate transaction costs involved, not to mention the yield "penalty" associated with Treasury securities.

Call Exposure Enhancements

The option-adjusted duration of a callable bond is the average of the model duration, if rates rise and fall marginally. These durations under rising and falling rates can be quite different for bonds trading at a price where the bond changes from trading to maturity, to trading to call (or vice versa). The result is a situation where the bond's actual performance could be significantly different than expected given its beginning-of-period option-adjusted duration.

Generally, the greater the expected yield change, the greater is the desire for more call protection. For premium callable bonds (bonds trading to call), the empirical duration (observed price sensitivity) tends to be less than the option-adjusted duration, resulting in underperformance during periods when rates are falling. For discount callable bonds (bonds trading to maturity), the empirical duration tends to be greater than the option-adjusted duration, resulting in underperformance in rising-rate environments. Any large deviations from the index exposure to call risk should recognize the potential significant tracking implications and the market directionality of the bet.

MEASURING SUCCESS

Of course, you can't manage what you can't measure. Managers understand this, but often find themselves without the proper measurement tools. Specifically, they lack accurate ways to gauge the extent of their bets, and the value added or lost from these bets. We've already covered measuring the extent of the bets in this chapter's sections on risk factors and enhancements. In this section, we'll explore how to measure whether any value has been added—and, if so, where the added value came from.

Outperform Adjusted Index Returns

Returning to the sailing theme, it's always critical to understand how the portfolio boat is faring against the index boat. Is the portfolio gaining any ground on the index? To evaluate relative performance, the portfolio returns must be adjusted for pricing, expenses, and transaction costs for growth and rebalancing. Pricing is a key consideration, especially in enhanced indexing, where deviations versus the index are small and pricing errors can hide valuable information. If a Barclays Capital Aggregate Bond Index is used as the benchmark, the portfolio needs to be repriced with Barclays prices. Small differences in either the pricing time or the

pricing matrix may result in significant differences (among pricing services) in periodic returns over short measurement periods. Over longer periods, these pricing differences will wash away. For value-added measurement purposes, though, periodic pricing accuracy is critical.

Since the index does not have transaction costs associated with asset growth, principal reinvestment, or income reinvestment, accurate adjustments to portfolio returns are needed to account for these differences. A simple way is to maintain a trading log with implied transaction costs as a percentage of total portfolio assets. The periodic summation of these implied costs provides a good estimate of tracking error drag associated with growth and income reinvestment.

Finally, an adjustment for expenses is required. As we discussed earlier, keeping expenses low is a simple way to enhance returns. Nevertheless, portfolio returns should be "grossed up" by these expenses to keep the portfolio on an equal footing with the index for measurement purposes.

Exhibit 49–17 shows the monthly *adjusted* tracking of a large bond index mutual fund, which in this example is managed against the Barclays Capital Aggregate Bond Index. If the enhancement sources are many and of a controlled nature, it's expected that the average tracking difference will be small and usually positive. During periods of extreme market stress or spread volatility (for example, the 2008 credit crisis), the enhancement strategies are likely to result in increased tracking differences. As shown in the exhibit, the monthly tracking differences during this experience were small (between +13 basis points and –4 basis points) and mostly positive. Exhibit 49–18 shows a rolling 12-month summation of the monthly *adjusted* tracking differences. An enhanced indexing strategy that has good risk management and diversified enhancements should be able to consistently outperform the index during most periods. Falling below the index return over the 12 months would most likely be the result either of not matching the index risk properly, of enhancement strategies that were not adequately diversified, or of significant market stresses

EXHIBIT 49–17

Consistent Positive Tracking: Bond Index Portfolio versus Barclays Capital Aggregate Index Monthly Adjusted Tracking Difference

EXHIBIT 49–18

Consistent Positive Tracking: Bond Index Portfolio versus Barclays Index Trailing 12-Month Total Adjusted Tracking Difference

(three or more standard deviation events) adversely affecting the enhancement strategies.

Low and Stable Monthly Tracking Differences

The other measure of indexing success is how closely the portfolio is exposed to the same risk factors as the index. This can be measured by evaluating the rolling 12-month standard deviation of *adjusted* tracking differences of the portfolio versus the index. Exhibit 49–19 uses the same bond index mutual fund example used in Exhibit 49–18, managed against the Barclays Capital Aggregate Bond Index. If a portfolio is properly exposed to the index risk factors, the standard deviation will be low and stable over most periods, as we see. Periods of excessive market stress and spread volatility may result in higher standard deviations of tracking differences. However, the increases should be roughly proportional to the spread volatility increase or explainable by idiosyncratic credit risk (sample risk).

EXHIBIT 49–19

Tight Tracking Standard Deviations Bond Index Portfolio versus Barclays Capital Index—Trailing 12-Month Standard Deviation of Adjusted Tracking Difference

Consistent Positive Information Ratios

The information ratio is a good way to evaluate enhanced indexing success. This measures the amount of value added versus the index relative to the risk taken. It can be calculated by dividing the trailing 12-month tracking difference (adjusted for expenses, pricing, and transaction costs of growth) by the annualized trailing 12-month standard deviation of monthly adjusted tracking errors. An effective and diversified enhanced indexing strategy should keep this ratio in the range of 1 to 3 over most periods. Exhibit 49–20 shows a consistent positive information ratio from the same mutual fund example we used in the past few exhibits.

Detailed Performance Attribution

A manager needs excellent performance attribution tools to accurately measure the success of risk factor management and the enhancement strategies. The performance attribution analysis should attribute tracking error to term structure factors, sector bets, quality bets, and issue selection across sectors and qualities.

The term structure attribution should be analyzed at the portfolio level versus the index. The sector and quality attribution (allocation and issue selection) should be analyzed at the sector and subsector levels (detailed sector and maturity categories) with the ability to drill down to issue-level detail. Issue performance should be risk-adjusted (versus Treasury equivalent returns) with subsector, sector, and portfolio returns rolled up from the security level. This level of attribution will provide the manager with the tools to measure, with precision, the risk matching and return enhancing strategies. The result: winning the race against both the index and most managers.

EXHIBIT 49–20

Consistent Positive Information Ratio Bond Index Portfolio versus Barclays Capital Aggregate Index Trailing 12-Month Information Ratio

KEY POINTS

- Full replication of a broad bond index is inefficient, if not impossible.
- Active bond managers intentionally position the portfolio with mismatches in risk factors in an attempt to add value above the index return.
- The core/satellite approach often uses low cost index strategies for the core portfolio and a variety of higher cost active strategies for the satellite strategies.
- The satellite portion of a portfolio focuses on the less liquid sectors which are expected to have lower correlations with the broad liquid core and where issue selection is expected to add value.
- Reasons to index bond include broad diversification, low cost, competitive performance, consistent relative performance, market performance predictability, and a time-tested record of success.
- In selecting an index for a given risk level, generally a broader index (sectors, maturities, issuers, etc.) is better than a narrow index.
- Subindices of a broad index can be created to capture different risk/return profiles (e.g., varying durations, varying credit exposures, etc.).
- For investors who are risk-averse (regarding possible loss of principal), a short-term or intermediate-term index is more appropriate than a long-term index.
- If stability and durability of income are the primary concerns, the long-term portfolio is the least risky, and the short-term portfolio the most risky.
- The primary bond index risk factors are portfolio adjusted duration, portfolio key rate duration exposures, portfolio sector and quality exposures (in percent and contribution to duration), mortgage coupon and maturity exposures, and issuer diversification.
- Since index returns are not adjusted to expenses and transactions costs, enhancements are needed just to provide a net return equal to the index.
- Return enhancements to help offset index portfolio management and transaction costs include lowering management and operating costs, issue selection strategies, yield-curve strategies, sector/quality strategies, and optimal call exposure strategies.
- Measuring success entails evaluating value added relative to a benchmark in the context of risk assumed relative to the benchmark.

Most fixed income portfolios are managed relative to a benchmark. Depending on the portfolio's investment objective and style, the role of the benchmark varies. At one end of the spectrum are passive indexed portfolios that strive to match benchmark risk exposures, and returns, as closely as possible. At the other end are active portfolios with high risk tolerance that maximize outperformance by investing freely outside the benchmark that serves only as a nonbinding reference point. The majority of fixed income portfolios fall somewhere between these extremes. Typically, a sponsor, an investment committee, a chief investment officer, or some other party that sets the investment objective specifies both the benchmark and the permissible deviations from it. The portfolio manager is then judged by the achieved outperformance versus the benchmark, and the amount of risk taken to generate this outperformance.

For the portfolio manager, the benchmark represents the zero-risk position. Over time, unless the manager deviates substantially from the benchmark, the portfolio's absolute performance will be determined largely by the choice of the benchmark. Consequently, the choice of a portfolio's benchmark is very important.

There is an ever-growing number of bond market indexes published by the leading investment banks and data providers. Often, an appropriate

benchmark can be selected from this wide array of indexes. But there are many cases when none of the ready-made indexes serves the goals of the investor or plan sponsor. To ensure that the benchmark correctly reflects a given investment opportunity set and constraints, an existing index may need to be modified. Sometimes, a new, highly specialized index needs to be constructed. Finally, for some investors, the right benchmark may not even be a traditional total-return market index.

Fixed income markets are extremely diverse, so most indexes tend to include hundreds or thousands of securities. The sources of risk affecting fixed income securities are equally diverse and often difficult to analyze. These conditions turn even relatively straightforward portfolio tasks into complicated endeavors. For most portfolios, a seemingly trivial problem of "buying the benchmark" means selecting a relatively small subset of constituent securities while ensuring somehow that its behavior will be reasonably similar to the broad universe. Understanding portfolio risk versus a benchmark is equally complicated because of the many risk dimensions and intricate interactions among them.

As a result, essentially all functions of the bond portfolio management process are aided greatly by robust quantitative methods. This chapter reviews some major issues facing bond portfolio managers, as well as quantitative approaches for dealing with them: selecting and customizing a benchmark, analyzing portfolio risk and performance, replicating benchmarks, and optimizing portfolio structure to improve its risk-adjusted performance.

SELECTION AND CUSTOMIZATION OF BENCHMARKS

Financial literature lists several desirable qualities for performance benchmarks. A good benchmark is investable, transparent, known in advance, and diversified. However, it is not always possible to achieve all of these goals. While these are all important attributes, first and foremost, the benchmark should be *appropriate*. An appropriate benchmark matches the required strategic allocation of portfolio assets, so that the portfolio's performance will be broadly consistent with the investor's overall objectives. A benchmark should also be investable so that a manager can "buy the benchmark" if and when he so decides. When comparing portfolio performance to the benchmark, it is critical to know when any difference owes to the manager's decisions and not to any in-built mismatches beyond the manager's control. Any constraints that limit the portfolio opportunity set must be reflected in the benchmark as well.

An index may provide an accurate gauge of the performance of a particular segment of the fixed income markets, but that does not necessarily make it an appropriate benchmark. For example, while the Barclays Capital U.S. Aggregate Index is a widely used benchmark for the U.S. investment-grade fixed income market, the average duration of this index (4.59 as of 10/31/10) may make it unsuitable for portfolios funding long-duration liabilities.

Reflecting Investor Opportunity Set and Constraints

When an investment policy requires specific allocations to certain asset classes or imposes other restrictions such as a duration target, a customized index may be a more appropriate benchmark. In the simplest case, a customized index merely changes relative weights of standard components while still including all securities in the standard index. Often, investment policy may impose a minimum credit-rating threshold on the securities that the portfolio can buy. Limitations may be placed on maximum exposure to an industry, country, and so on. Many other bond attributes, such as minimum or maximum maturity, age, coupon, etc., may also be controlled, requiring corresponding changes to the benchmark. In all cases, though, the goal should be to keep the benchmark as broad-based and well-diversified as possible while still meeting all the investment policy requirements. However numerous the modifications to the original market-based index, one important benchmark property always should be preserved: objectivity. The benchmark should be based on a set of rules specified beforehand and kept constant. The rule-based nature of a benchmark also allows for a historical analysis of its past behavior. Such analysis can be quite useful at the stage of selecting a benchmark.

One widely used method to achieve outperformance is to invest outside the benchmark. Such investments (e.g., high-yield credit or emerging market debt) frequently are referred to as "core-plus." Even when the exposure to core-plus assets is constantly present in the portfolio, many managers still prefer to keep such assets out of the benchmark. Their motivation, of course, is to keep this potential source of outperformance at their disposal. However, a case can be made for inclusion of frequently used core-plus assets into the benchmark. First, by including these assets in the benchmark, the manager's relative performance will be more fairly measured if the manager has a persistent allocation to these assets. Second, it is often difficult to "short-sell" core-plus type assets. Yet a manager who has expertise in these markets can benefit from a short position just as much and as frequently as from a long position. The only way to effectively short such assets is to underweight them versus the benchmark. This, of course, is only possible when they are included in the benchmark. Such a benchmark decision should be made only after ensuring that with the inclusion of these asset classes, the benchmark will remain appropriate for the portfolio's investment objective and style.

Targeting Duration/Cash-Flow Profile

Sometimes a customized benchmark is necessary not because of sector, quality, or other allocation constraints but because the portfolio is expected to have a particular term-structure exposure. For example, some portfolios are managed to provide a particular cash-flow stream to fund a set of liabilities. At the simplest level, portfolio duration may be kept equal to the duration of the liability stream. Dedication is another widely used method for ensuring the necessary cash-flows

while (usually) minimizing the portfolio cost. Of course, funding the future liabilities is the main investment objective in such cases. Yet investment policies of liability funding portfolios can be quite liberal, providing an opportunity for outperformance while still ensuring sufficient cash flows.

Such portfolios would benefit from a diversified benchmark with a cash-flow profile that matches the expected liability stream and at the same time fully reflects the manager's opportunity set. Consider, for example, a liability funding portfolio that is free to invest in any security in a credit index. An appropriate benchmark for such a portfolio could match the sector and quality distribution of the index while also matching the cash-flow profile of the liabilities. Such a "liability-based" benchmark retains many of the desirable attributes of a broad market-based index: it is objectively-defined, so the portfolio manager can stay neutral to it, and its returns are calculated using market prices. Because this benchmark consists of marketable securities, its performance can be calculated and published by a third-party index provider.[1]

Even outside the asset/liability context, many fixed income portfolios are managed with a specific duration target. If this target is not close to the duration of any standard (published) index, an appropriate benchmark may be constructed as a blend of two published indexes, one of which is longer and the other shorter than the target. Although the weights needed to achieve a desired duration may have to be adjusted at regular intervals, they typically remain fairly stable for indexes that consist mainly of option-free securities.

Things get more complicated for portfolios containing a large proportion of securities with embedded optionality. Duration of such portfolios is likely to be unstable, changing in response to interest-rate movements. For example, the duration of mortgage-backed securities (MBS) can be quite volatile. If maintaining a stable duration is an important requirement, managers may engage in such techniques as delta hedging to overcome the effect of negative convexity and keep duration relatively constant. Hedging techniques entail various costs, from the more obvious transaction costs to the less obvious but potentially more significant "whipsaw" costs.[2] It is unfair to judge the performance of a manager who must engage in costly delta hedging against a benchmark that does not bear similar costs. Two possible solutions are: to apply delta hedging to the benchmark; or to construct a "constant duration" index that provides a fairer benchmark for a delta-hedged mortgage portfolio.[3] An example of such a benchmark could be a market-weighted

1. For a detailed discussion, see Chapter 10 in Lev Dynkin, Anthony Gould, Jay Hyman, Vadim Konstantinovsky, and Bruce D. Phelps, *Quantitative Management of Bond Portfolios* (Princeton, NJ: Princeton University Press, 2007).
2. Negative convexity causes duration to decline with falling rates. The term *whipsaw* refers to having to add duration after rates have just fallen and prices have gone up and to shed duration after the opposite movement.
3. Lev Dynkin, Jay Hyman, Vadim Konstantinovsky, and Ravi K. Mattu, "Constant Duration Mortgage Index," *Journal of Fixed Income,* 10:1 (2000), pp. 79–96.

MBS index dynamically hedged, according to a set of rules, with a liquid leveraged overlay of Treasuries or futures contracts.

Asset-Swapped Indexes

Some investors can take credit positions but are required to match the interest rate exposure to their funding source (e.g., three-month LIBOR). For example, some bank and insurance investment managers must manage their portfolios to a short duration target for asset/liability management purposes but are free to exercise their credit skills in asset selection. Leveraged investors often concentrate on credit exposure but minimize interest-rate exposure by managing the portfolio duration to the short-term LIBOR funding. In an environment of moderate credit-spreads and low interest rates (and worries about rising rates), traditional total return managers are also likely to keep durations very short while maintaining an overweight to spread sectors. These managers want to exercise their credit skills but avoid term-structure risk.

The most straightforward way to create and maintain such exposures is to turn to the floating-rate note market. However, given limited issuance, this may create an unintended concentration of systematic sector exposures or issuer idiosyncratic risk. Ideally, the manager would want to match systematic spread-sector risks (i.e., credit quality and sector exposures) of a broad credit market index while simultaneously removing exposure to all systematic Treasury key-rate risk factors except, perhaps, the shortest (e.g., three or six-month) key rate. The challenge of designing a benchmark for such a portfolio is to ensure a very short Treasury duration and at the same time match the overall index allocations to the credit sectors.

To exercise their spread-sector timing skills while minimizing interest-rate exposure, investors can buy fixed-rate spread assets on an "asset-swapped" basis. Asset swaps are combinations of a fixed-rate bond (and its credit exposures) and an interest-rate swap that exchanges the fixed-rate coupons for floating-rate coupons. An asset swap gives an investor an opportunity to take spread-sector exposure with little term-structure risk.

There are no formal indexes of asset swap performance. To benchmark an asset-swapped portfolio effectively, the benchmark must represent a "neutral" spread-sector allocation. Then the manager's deviations from neutral may lead to outperformance of the benchmark. Using three-month LIBOR as a benchmark is inadequate because LIBOR reflects only a single type of spread risk (i.e., swap spreads) and does not represent the wide array of spread-sector choices that may be available to the manager. An ideal design for asset-swapped portfolios is a floating-rate benchmark that reflects a diversified set of spread-sector exposures. One approach to constructing such benchmarks[4] starts with the creation, for each asset class, of a "mirror" swap index, which is a portfolio of interest rate swaps that has

4. For a detailed description of this methodology see *Quantitative Management of Bond Portfolios*, Chapter 12.

the same key-rate duration profile as that of the "mirrored" asset class. Then, short positions in these mirror-swap indexes are combined with long positions in the corresponding asset-class indexes, as well as with a long position in a short-term asset (e.g., one-month LIBOR). This creates "asset-swapped indexes" for all asset classes in the benchmark. Finally, individual asset-swapped indexes are merged into the final composite benchmark according to the portfolio's "neutral" allocations.

Book Accounting Based Indexes

Fixed income investors typically measure portfolio performance by calculating returns using market prices at the beginning and end of the performance period. Consequently, the portfolio's market value fluctuates with changing Treasury yields, spreads, and prepayments. Most standard fixed income indexes are market-return based, and many analytical tools make the same assumption about portfolios.

However, there is a large class of investors (e.g., insurance companies and banks) less concerned about short-term market fluctuations. They purchase fixed income assets to match a set of liabilities whose net present value is based not on market prices, but on book, or purchase, prices. Typically, these fixed income portfolios are relatively static. Investors expect the portfolio to earn an adequate spread over the cost of the liabilities, assuming that the assets do not default or prepay at a rate unanticipated at the time of purchase. Given that liabilities are valued using book accounting, these investors (and their regulators) need to measure asset portfolio performance similarly either by the portfolio's "book return," which is book income divided by book value, or the portfolio's "book yield," which is its internal rate of return calculated at time of purchase. However, how can such investors measure their investment skill when most indexes are market-return based?

Book accounting based investors can measure their performance relative to book accounting based indexes, or "BOOKINs," that are, in theory, replicable investment portfolios. For example, suppose that in January 2011, an investor restricted to assets in the Barclays Capital Aggregate Index must fund a newly acquired liability. The investor could passively invest in the January 2011 Aggregate BOOKIN. The composition of this BOOKIN is set to reflect the Aggregate Index as of January 2011, and its book yield and book return are calculated every month. Over the course of the month, the BOOKIN will generate cash-flow (coupon, prepayments, proceeds from maturities), which is reinvested in the February 2011 Aggregate Index. Consequently, by February 2011, the JAN11 Aggregate BOOKIN becomes a conglomeration of the initial investment in the January Aggregate Index plus a smaller investment in the February Aggregate Index. This process is repeated every month. The performance of the JAN11 Aggregate BOOKIN, expressed in book accounting terms, reflects what the investor could have achieved by passively investing in the Aggregate Index starting in January 2011, and thus can be directly compared with the book accounting performance of the investor's actual portfolio.[5]

5. For a detailed description of book accounting based benchmarks, see *Quantitative Management of Bond Portfolios*, Chapter 9.

Strategy-Based Indexes

Finally, some portfolio managers must operate under severe performance constraints such as "over the next three months generate as much return as you can, but don't lose any money!" Many official institutions manage their Treasury portfolios under such constraints. What is an appropriate benchmark for these investors? While a cash benchmark (i.e., zero duration) would not suffer any losses, it would severely limit income. In contrast, a longer duration benchmark would likely generate more income but put the portfolio at risk of losses over the holding period.

The right benchmark would have a duration that maximizes expected returns subject to the risk constraint. But, how to best generate expected returns to determine the benchmark? Using historical Treasury returns data is one approach. An advantage of historical returns is that they are non-subjective estimates of expected returns. However, historical returns are poor predictors of future returns. Another approach is to use expected returns embedded in the current term structure. These estimates are also non-subjective (i.e., "no-view") because they assume only that the yield-curve will remain unchanged. These no-view expectations reflect current market conditions whereas historical returns do not.

A benchmark can be constructed using no-view expected returns and historical volatilities to maximize expected return subject to a risk constraint of not having a return less than zero with a pre-specified probability. The solution to this optimization problem is a Treasury portfolio that would serve as the benchmark. The manager would then be responsible for outperforming it. Alternatively, the manager could simply hold the benchmark if he did not wish to take any risk. This "no-view" Treasury benchmark is an example of how benchmarks can be objectively designed to reflect investment goals and constraints.[6]

DIVERSIFICATION ISSUES IN BENCHMARKS

Issuer-specific risk is an important consideration in credit portfolios. Increasingly, though, benchmarks are also scrutinized for any embedded security-specific risks. Excessive exposure to individual issuers is a concern not just for portfolio managers. Plan sponsors now reexamine benchmark design and pay close attention to large issuer concentrations. This is a serious issue even for the users of very broad market indexes. As Exhibit 50–1 shows, as of October 2010, the top 10 issuers in the Barclays Capital U.S. Corporate Bond Index accounted for 23% of the overall market value. For some plan sponsors, this is too much security-specific risk. An asset manager benchmarked to this index may feel compelled to have exposure to some of these large-cap issuers because they have significant weights in the benchmark. Concerns about the high level of issuer concentration risk in some commonly adopted benchmarks led to a number of developments in benchmark design that attempt to mitigate this risk.

6. For a discussion of no-view optimization and benchmarks, see *Quantitative Management of Bond Portfolios*, Chapter 22.

EXHIBIT 50–1

Source: Barclays Capital

Issuer-Capped Benchmarks

A cap on the market-value weight that an issuer can have in the index limits exposure to the issuer's idiosyncratic risk. When such a cap (e.g., 1%) is imposed, every issuer's capitalization is checked against this ceiling. The market value in excess of the cap is "shaved off" and then distributed to all other issuers in the index in proportion to their market-value weights. Different caps can be chosen for various credit ratings, reflecting the differences in issuer-specific risk between higher and lower credit qualities. While issuer-capped portfolios have existed for quite a while, issuer-capped benchmarks are more recent and emerged in response to the increased levels of issuer-specific risk in credit markets.

Issuer-capped indexes seem very straightforward. However, the cap level and the redistribution rule can have a significant impact on the risk and return characteristics of an index. Some redistribution rules can limit the benefits of issuer capping by inadvertently introducing unfavorable sector-quality risk exposures relative to the uncapped index.[7]

For example, an "index-wide" redistribution rule allocates the "excess" market value across all non-capped issuers in the index in proportion to their weights. However, this may produce an index with very different (and most likely unintentional) sector and quality exposures compared with the uncapped index. For

7. For a discussion of issuer-capped credit benchmarks, see *Quantitative Management of Bond Portfolios*, Chapter 13.

example, the following table covering the period August 1989 through October 2010 shows that the index-wide redistribution rule in a 1% issuer-capped Barclays Capital U.S. Corporate Bond Index produces significant overweights in Baa-rated and industrial issues and a significant underweight to financials compared with the uncapped Corporate Index:

	Aaa-Aa	A	Baa	Industrial	Utility	Financial
Average	–2.62%	–0.39%	3.00%	3.17%	1.31%	–4.48%

This inadvertent introduction of potentially unfavorable sector-quality risk exposures can be avoided by a "quality-sector-neutral" redistribution rule that preserves the sector and quality profiles of the uncapped index.

Another side effect of capping large issuers in an index is the increase in weights of smaller ones. By construction, in a capped index the market-value weights of smaller issuers exceed their actual weights in the marketplace, sometimes dramatically so. This raises a practical concern that the available market supply may not allow the manager to match (if he or she so chooses) the required allocation in the issuer-capped index.

Issuer-capping has also been applied to sovereign indexes. The distribution of sovereign issuers is highly concentrated. For example, based on market value weights, Japan represents almost 32% of the Barclays Capital Global Treasury Index (as of 12/31/2010), and the U.S. almost 26%. Together, Japan and the U.S. comprise almost 60% of the Global Treasury Index. Within geographical regions these country weights are even larger, as Japan Treasuries account for over 90% of Asian Treasury bonds while U.S. Treasuries account for 92% of Treasuries in the Americas. The skewed distribution of sovereign issuers may make issuer-capping attractive to investors. However, as with issuer-capped credit indexes, care must be exercised when redistributing any excess capped market value.

A simple sovereign capping scheme of redistributing any excess market value above a cap level across all smaller sovereign issuers in the index does little to reduce the volatility of the index. This is because the excess capped market value gets proportionally reallocated to other countries that are closely related economically to the capped countries. A more productive sovereign capping scheme is first to cap the market value weight of economic regions, and redistribute excess market value across other regions. Then, cap individual sovereigns within a region and redistribute any excess capped market value within the region. Such a two-tier capping scheme reduces the volatility of the index, compared to the uncapped sovereign index, and does not hurt the index's performance.

An alternative sovereign capping scheme is to adjust index market value weights depending on the relative economic fundamentals across countries. For example, countries whose Debt/GDP levels are below average would have their

index market value weights increased, while those countries with above average debt levels would have their weights lowered.[8] Such "fundamental-based" weighting schemes have become more popular as sovereign creditworthiness has become less certain.

Despite these subtle issues, issuer-capped indexes are now a permanent fixture of the investment management landscape. With good judgment, investors can design issuer-capped indexes that meet their risk-management preferences in dealing with issuer-specific risk.

Swap-Based Benchmarks

A somewhat radical approach to dealing with issuer-specific risk in credit benchmarks is not to have this risk at all. Apart from the naive solution of adopting an all-Treasury benchmark, one popular type of benchmark is based on interest-rate swaps. Swaps offer excellent liquidity, a virtually unlimited market supply, limited idiosyncratic or "headline" risk, and an opportunity to capture some of the long-term spread advantage of investing in non-Treasury product. Swaps have been a key feature of the debt markets since the early 1990s. In fact, in several ways the swaps market is larger and more heavily traded than the U.S. Treasury market.

Swap payments are based on LIBOR, and therefore, the par swap rate curve can be viewed as a generic yield-curve for large, highly rated banks whose interbank lending rates constitute the LIBOR index.[9] Correspondingly, the swap spread (to the Treasury curve) is considered a generic proxy for high-grade credit spreads. (While the swap spread does not reflect counterparty risk, this can be effectively eliminated through collateral management.)

This relationship between interest rate swap spreads and high-grade credit-spreads has prompted some investors to consider swaps as total return benchmarks for their credit portfolios. However, unlike returns on regular fixed income securities, returns on swaps are not directly observable in the marketplace. In addition, while cash fixed income securities have an underlying market value that serves as the base on which to calculate returns, par swaps at initiation have zero market value. While swap yields and spreads are available from many sources, swap returns are not. To create total return indexes for the swaps market, a new index methodology is needed.

The Barclays Capital interest rate swap index methodology[10] relies on the creation of hypothetical constant-maturity swap "securities" from the swap curve. At the start of every month a set of par receive-fixed swaps is identified with swap

8. For a detailed description of one such index, see "Barclays Capital Fiscal Strength Weighted Bond Indices", Barclays Capital, July 2011.
9. A list of the banks that currently participate in the "LIBOR panel" for U.S. dollar LIBOR and other currency deposit rates is available from the British Bankers Association's Web site at www.bbalibor.com.
10. Lev Dynkin, Yuri Greenfield, and Dev Joneja, "The Lehman Brothers Swap Indexes," *Journal of Fixed Income* 12:2 (2002), pp. 28–42.

rates taken from the specific maturity points on the swap curve. To create, say, the 10-year swap index the 10-year par swap is paired with a cash investment in three-month LIBOR equal to the notional amount of the swap. Over the course of the month, the mark-to-market return of the 10-year swap is combined with the mark-to-market of the LIBOR deposit, divided by the initial notional value, to produce a 10-year swap index return. There are as many swap indexes as there are maturity points on the swap curve. There are interest rate swap indexes not only for USD, but for other currencies as well (e.g., EUR, GBP, and JPY).[11]

The individual swap indexes can be combined to produce a swap index with any desired term-structure profile (e.g., to match a particular liability duration target). Recall the earlier discussion on asset-swapped benchmarks where each asset class had an associated swap index (the mirror swap index) with a matched key-rate duration profile. A credit portfolio manager who has a swap index as a benchmark is completely free to hold only those credits which he thinks will outperform and to avoid credits expected to underperform duration-matched swaps. Credits on which the manager is neutral or has no view need not be in the portfolio at all. In contrast, if the manager's benchmark is a market index, he is under pressure to have at least some exposure to the largest issuers in the benchmark. Even when the manager has a negative view on a large issuer in the corporate index, he is unlikely to hold a zero weight because that creates a large active bet against the benchmark.

Downgrade-Tolerant Benchmarks

Even in periods of severe spread volatility, many investors retain a persistent allocation to credit in the belief that given sufficiently long time, credit bonds earn a meaningful spread premium over comparable duration Treasuries. Credit-spread premium refers to any excess return net of realized default losses, not including the impact of spread changes. A buy-and-hold credit investor earns the spread premium to maturity and ignores mark-to-market volatility in the interim.

But do investors indeed capture this credit-spread premium? In theory, they do, as long as they maintain a hold-to-maturity allocation to credit. In reality, however, most investors use a market benchmark to represent their credit allocation. In the case of Barclays Capital investment-grade indexes, for example, the index rules stipulate that a bond downgraded below investment grade be dropped from the index. Accordingly, portfolios benchmarked to the index have to sell these bonds. Usually, this is precisely when the spreads of such bonds are particularly wide, often wider than justified by any subsequent default losses. This bad timing may cause index-benchmarked investors to forfeit, at least partially, the credit-spread premium.

11. In addition, Barclays Capital publishes a set of CDX and iTraxx swap indexes which measure the total return of a funded investment ("selling protection") in these popular credit default swap portfolio indexes.

EXHIBIT 50–2

Estimated Annual Credit-Spread Premium, 1990–2009, % per Year

Source: Barclays Capital

An alternative is to allow managers to hold on to downgraded bonds and choose their own timing in selling such bonds.[12] Such a "downgrade-tolerant" Corporate Index has captured a spread premium almost 80% higher than the standard index. Exhibit 50–2 plots a yearly comparison between the two, for the period from 1990 through 2009. The downgrade-tolerant index delivers a higher premium in every one of these 20 years, with virtually the same risk profile as the standard index.[13]

These results suggest that if managers are allowed to hold on to bonds that the Corporate Index discards, they should be able to harvest a considerably higher spread premium and significantly improve their performance versus the benchmark.

PORTFOLIO ANALYSIS RELATIVE TO A BENCHMARK

The selection of the investment guidelines and appropriate benchmark marks the beginning of the portfolio management process. Once a portfolio is established,

12. The performance varies greatly across fallen angels, so there are no clear decision rules as to the best time to sell them. However, there is an overall improvement in the risk-adjusted forward performance of fallen angels as the permitted holding period is increased.
13. See: Kwok Yuen Ng and Bruce D. Phelps, "Capturing the Credit-Spread Premium," *Financial Analysts Journal*, 67:3 (2011), pp. 63–75.

investors continually monitor its positioning relative to the benchmark. Apart from investing new funds, periodic transactions help to maintain desired exposures and express changes in market outlook.

Certain portfolio monitoring activities are typically performed at regular intervals (say, a calendar month) and in a set sequence. Other analyses are performed as the need arises and not necessarily in a fixed order. Yet, however different the operational details might be, there are certain common functions that portfolio managers must perform and certain types of tools necessary to carry out these duties. Typically, at the start of a performance period, managers will use forward-looking, or *ex-ante,* analytics to create and ascertain the desired portfolio positioning. At the end of the period, managers will use backward-looking, or *ex-post,* analysis to review and explain the realized performance which, in turn, guides portfolio adjustments.

Analyzing Portfolio Risk: A Cell-Based Approach

The most obvious way to analyze portfolio-versus-benchmark risk is a structural comparison of the two by partitioning them into a matrix of cells. Different choices of partition variables put the focus on different aspects of portfolio composition. Corporate portfolios, for example, are likely to be divided by quality and industry category (e.g., basic industry, consumer cyclical, and energy). Segmenting by duration highlights the yield-curve exposure. The amount and quality of information a portfolio manager can derive from such reports depend on the appropriateness of the chosen risk dimensions and on the portfolio and benchmark attributes (beyond market-value percentages) available for comparison.

The fundamental assumption behind the use of structural reports is, of course, that the contribution of a mismatch in a given cell to the overall portfolio-versus-benchmark risk is primarily a function of the magnitude of the mismatch and the weight of the cell. This assumption is not unreasonable. Certainly, a portfolio that matches its benchmark in all cells (along *all* possible dimensions) is risk-neutral to the benchmark.

While the simplicity of such analysis is attractive, there are two major problems with its basic assumption. First, the risk consequences of a particular mismatch depend not only on its apparent magnitude but also on its nature, i.e., the volatility of the underlying exposure. A mismatch in spread duration contribution of 1.0 in Aa financials has a very different risk than the same-size mismatch in Baa telecom. Granted, some experienced portfolio managers may have a feel for the portfolio performance implications from the magnitudes of individual mismatches.

However, the second problem is equally important and, arguably, more difficult to compensate for with experience. The cross-correlation among the multiple sources of risk in a portfolio makes judging overall risk a daunting one without quantitative tools. Two mismatches in two different cells, each entailing significant risk in isolation, may cancel each other if low (or even negative)

correlation between them reduces their joint contribution to risk. Conversely, a few mismatches that could easily be ignored individually may represent a serious risk if the correlations among them are high. Needless to say, when the number of mismatches reaches dozens, as it can even in relatively simple portfolios, finding the common risk denominator by "eyeballing" the structural mismatches is unrealistic.

Analyzing Portfolio Risk: Multifactor Risk Models

One reliable approach to quantifying a portfolio's active risk (i.e., risk versus benchmark) is multifactor risk analysis. Its primary goal is to help managers to structure portfolios with desired risk exposures relative to the benchmark. As such, it is generally used not as an *ex-post* control tool but rather as an *ex-ante* tool for portfolio structuring. One obvious need is to measure the expected risk of return deviation in portfolios that track a benchmark. Another is to form a reliable estimate of risk for active managers with a particular outperformance, or "alpha," target. There is a well-established consensus among investment professionals regarding realistic levels of *information ratio,* or risk-adjusted outperformance, versus the benchmark. A realized information ratio above 0.5 generally is considered to be quite high, with 1.0 often seen as a practical upper limit. As a result, quantifying active risk allows managers to test the feasibility of a specified alpha target. For example, a portfolio with an alpha target of 50 basis points per year should be allowed an active risk somewhere in the range of 50 to 100 basis points per year. If, as a result of policy constraints, the projected risk is estimated to be much lower, the manager should make a case for either relaxing portfolio constraints or revising downward the alpha target.

Active risk has *systematic* and *idiosyncratic* components. The former is a result of the differences between the portfolio and benchmark sensitivities to common market *risk factors* (e.g., movements of the key rates, credit sector spreads, or volatility). The latter, sometimes referred to as "diversifiable risk," reflects unequal exposures (usually overweights in the portfolio) to individual issuers and can be present even when all systematic exposures are eliminated. This type of risk reflects residual spread movements of individual issuers, not explained by anything that happens to their peer group. Apart from the risk of typical idiosyncratic spread movements, there is default risk which is particularly important in lower-quality credit portfolios. For example, in the Barclays Capital risk model, default risk is modeled and reported separately from market risk. Conceptually, default risk contains both systematic and idiosyncratic parts. Correlated defaults across different issuers create a systematic risk component. To the extent that defaults are uncorrelated and reflect unusual events specific only to a particular issuer, the default risk is idiosyncratic risk. Separating the systematic and idiosyncratic components of default risk is quite difficult.

To quantify the systematic component of market risk, multifactor risk models use historical volatilities and correlations of a relatively small set of risk factors. These are processed into a *covariance matrix* that is the cornerstone of the model. The idiosyncratic component of active risk is quantified by measuring the differences between the portfolio and benchmark concentrations in a specific issue or issuer. These weight differentials are then multiplied by idiosyncratic spread volatilities specific to a given issuer or its peer group.

These risk components are combined to produce the key output of such models—*tracking-error volatility* (TEV), defined as the projected standard deviation of the monthly return differential between the portfolio and the benchmark. TEV is an extremely useful measure because it provides a common unit for many different sources of risk, enhancing comparisons of diverse exposures and greatly facilitating portfolio risk management and risk budgeting. Well-developed models not only compute TEV but also provide useful information on its components, for example, detailed analysis of the TEV sources, their relative contribution to the total, and their interdependence.[14]

Of course, the reliance on historical observations exposes the multifactor analysis to criticism that risk-factor correlations are unstable and depend (as do volatilities) on the economic cycle. These concerns, however, are easily addressed.

Different historical periods can be viewed as more or less relevant to the current environment. Some asset classes evolve over time, and their risk characteristics change. For example, the dramatically increased refinancing efficiency in the U.S. residential mortgage market made MBS prepayment history up to the early 1990s largely irrelevant for estimating prepayment risk in subsequent periods. Economic and market conditions also may justify emphasizing a particular historical period while downplaying others. Risk models can accommodate these risk dynamics. One mechanism is to impose time decay on the historical data series to give greater weight to more recent data.

The idiosyncratic component of active risk presents a bigger challenge to history-based risk models. To quantify the issuer-specific risk, a model needs estimates of residual spread volatility in all market segments. These estimates can be derived only from the historical time series of individual securities' residual returns; that is, parts of each bond's return unexplained by all the systematic risk factors. This requires a large body of individual security-level historical data.

As with systematic risk, there is the issue of choosing a relevant historical period for the idiosyncratic risk estimation. Conservatism is usually a good rule of thumb. After a spike in issuer-specific volatility, such as the one that happened in the U.S. credit market in 2008, a risk model needs to "learn" quickly from recent experience. Applying time decay to the historical data accomplishes this and makes the model produce higher estimates of idiosyncratic risk going forward. Sometimes, however, a risk model should pay less

14. *Quantitative Management of Bond Portfolios*, Chapter 26.

attention to recent experience. After a long period of calm, the model should revert to the equal weighting of historical data to avoid underestimating issuer risk.

History-Based Scenario Analysis

In one form or another, scenario analysis is used widely by portfolio managers to study portfolio (and benchmark) behavior in various yield-curve, spread, volatility, prepayment, or exchange-rate environments. Managers focus on what they consider the most likely scenarios, or unlikely but potentially damaging scenarios. Scenario analysis complements multifactor risk analysis. It allows managers to stress-test benchmarked portfolios by subjecting them to extreme conditions ("three-standard-deviation events") not necessarily consistent with the history underlying the risk model. Such analysis may highlight potential sources of return deviations that do not manifest themselves under normal (by historical standards) circumstances.

When using scenario analysis, investors usually make explicit forecasts for specific, observable market dimensions: key interest rates, credit-spreads for certain market sectors, particular exchange rates, and such. It is very difficult, however, to formulate scenarios that are consistent in both direction and magnitude across many different market sectors and to estimate the probability of such scenarios. This is similar to analyzing risk simultaneously along many dimensions. Thus the solution also can be the same as in multifactor risk models. A covariance matrix estimated from historical observations can be used to build "maximum-likelihood scenarios." Such scenarios incorporate a few explicit forecasts provided by the investor and then infer historically-consistent realizations (forecasts) for all other factors in the matrix. Then the full set of stated and derived factor forecasts is translated into expected returns for individual securities.

Explicit forecasts may represent unlikely scenarios. For example, the projection of a one-month yield increase of 50 basis points (or more) represents a 2.3% probability event if the historical yield volatility is only 25 basis points per month (assuming a normal distribution). Similarly, historical correlation patterns would not support an expectation of credit-spread widening at the same time with an increase in Treasury yields because yield and spread changes typically are negatively correlated. A scenario-generation model can be made to assess the likelihood of an explicit forecast in light of the covariances that underlie the analysis and to allow a rescaling of forecasts to meet pre-specified likelihood targets. The views can be relative as well as absolute. A yield-curve slope forecast is an example of a relative forecast because it does not express an opinion on the overall direction of interest rates. Individual forecasts can be accompanied by degrees of confidence in them. For example, investors usually are more confident in their views on credit-spread movements than on currency and

interest-rate changes. A robust scenario analysis framework should be able to incorporate this information.

Attribution of Portfolio Performance Relative to a Benchmark

A comprehensive performance-attribution framework must account for all potential sources of portfolio performance and quantify the contribution from each of these sources. Performance attribution of past returns is perhaps the most important tool that asset managers can use to substantiate their claims on expertise in a given style of investment. If, for example, an investment fund claims to be adept at finding undervalued credits, performance attribution can be used to determine what share of the fund's past outperformance was due to credit picks. Unless there is hard proof that the generated returns came from the advertised source, investors may worry that superior performance might have been luck rather than skill and may, in fact, be a sign of imprudent risk taking.

Asset management companies also benefit from using performance attribution in the internal analysis to help determine their skill in managing different kinds of exposures and the areas that need improvement. Sources of achieved outperformance should be matched with sources of ex-ante risk. Quantitative analysis of return deviations from the benchmark may point out unintended portfolio exposures that need to be corrected. This is particularly important for large funds with decentralized decision making in which separate groups or individuals are responsible for yield-curve positioning, sector and quality allocations, and name selection. Performance attribution can help evaluate individual manager performance in such an organization. Flexibility is critical in this analysis. A performance-attribution framework will only be useful (and used) if it is aligned with the actual decision-making process behind the portfolio investments. This process differs across firms and may vary over time within a single firm.

For multicurrency portfolios, the analysis normally starts at the global level, where outperformance can be traced to two basic sources: exchange-rate exposures and asset allocation exposures to different markets. The ability to implement currency hedges as an overlay using FX futures or forwards empowers managers to separate the asset allocation and currency allocation decisions. The attribution framework should explain the performance due to each.

After multicurrency outperformance is assessed, portfolio positions generally should be segregated by currency, and the performance of each single-currency portfolio evaluated separately (versus appropriate single-currency benchmarks). In a developed fixed income market, such as the United States, local returns can be divided into three main components: Treasury (yield-curve), volatility, and spread.

The Barclays Capital performance-attribution system relies on the key-rate duration[15] methodology to compute outperformance owing to the Treasury curve positioning. Both the portfolio and the benchmark are replaced by hypothetical portfolios of Treasuries with exactly the same yield-curve exposures, that is, with matching key-rate duration profiles. Then the returns of these "Treasury-matched" portfolios are compared. Any difference comes exclusively from their disparate curve exposures. The bonds in the Treasury-matched portfolios usually are not real securities but rather points from the par yield-curve, and contribute no pricing noise (such as owing to the richness of on-the-run issues). The model breaks down this component of outperformance even further to individual key-rate exposures.

A shift in implied volatility affects prices of bonds with embedded optionality. Quantifying outperformance owing to differences in volatility exposure requires a good term-structure model that can estimate the implied volatility of the Treasury curve and the analytics to compute volatility sensitivity (or vega) for all securities in the portfolio and in the benchmark.

Outperformance owing to spread exposure can be broken into an asset allocation part (asset class, sector, industry, quality, etc.) and a security-selection part. The former occurs when the portfolio had larger allocations to winning asset classes (or smaller to losing) than the benchmark. Security-selection outperformance comes from picking names that outperform their peers. Both measures depend strongly on the definition of asset classes or security peer groups.

Performance attribution is one of the most complex elements in a suite of methodologies and tools that modern asset managers need. There are many technical points and subtleties, such as aggregating daily results, accounting for intraday trading, and dealing with pricing and return conventions that differ between the portfolio and the benchmark.

QUANTITATIVE APPROACHES TO BENCHMARK REPLICATION

Besides index funds whose investment mandates explicitly call for tracking benchmarks with the minimum possible deviation, "buying the benchmark" is often a reasonable tactic even for managers who normally pursue active strategies. For example, in times when managers have no definite views on particular segments of the market, matching index returns in those segments is a sensible strategy. Sometimes, when managers have accrued significant outperformance before the year is over, they decide to switch to passive benchmarking for the rest of the year to preserve their gains. Finally, investors sometimes use so-called proxy portfolios that replicate broad market indexes for modeling purposes rather

15. While a single duration number measures price sensitivity to a parallel shift of the entire yield-curve, key-rate durations measure sensitivity to changes in rates at various points (key rates) along the curve, holding the rest of the curve unchanged.

than for direct investment. The main reason usually is to apply the same in-house models (e.g., prepayment models) to both the portfolio and the benchmark, eliminating "model noise" that can be quite significant. Sometimes it is not feasible to include the actual benchmark in the analysis because of constraints on either processing time or data availability. Computer-based analysis gets simpler and faster when applied to a small set of well-priced securities as opposed to potentially thousands of bonds in an index. Hence, the term *proxy portfolios*.

As pointed out earlier, the replication of a diverse market index that has multiple sources of return is not a trivial task and requires complicated techniques and tools. There are two main techniques: replication with actual, or "cash," securities and replication with derivative instruments (e.g., futures and swaps). The replication strategies vary greatly, reflecting diverse characteristics of various fixed income markets, as well as objectives and constraints of different investors. For example, in markets with high idiosyncratic risk, it is relatively more important to match the issuer distribution of the benchmark. Where systematic risks dominate, the replication techniques should pay close attention to matching benchmark allocations along the important risk dimensions. For portfolios experiencing dynamic cash inflows and outflows, replication strategies using derivatives may be preferred because of their liquidity and low costs. Derivatives replication is also popular with investors engaged in "portable alpha" strategies that use liquid derivatives that require little or no cash investment to replicate index returns and then invest the available cash outside the index in overlay strategies to gain alpha.

Of course, the simplest way to replicate an index is to buy most of its securities. However, this method is practical only for the few largest index funds that have had years to accumulate many of the index issues. For smaller and newer portfolios, maintaining the required proportions of a large number of bonds would lead to buying and selling odd lots, with limited availability, and overwhelming transaction costs. Furthermore, this strategy is appropriate only for portfolios that intend to remain neutral versus the benchmark for a long time.

For most investors, cash replication involves buying a small set of index bonds to track the index. The problem of selecting the right subset of index securities is solved by one of two basic approaches: cell matching (stratified sampling) or tracking error minimization using a risk model. The relationship between the two parallels closely that between the cell-based and the risk-model approaches to measuring portfolio risk.

REPLICATION WITH CASH INSTRUMENTS: STRATIFIED SAMPLING

Sampling is the "common sense" approach. To replicate an index, one attempts to match its allocation to each important segment with a few securities. In the simplest case, the market-value weight of holdings in a particular segment of the portfolio is set to match the index weight. More often, holdings are selected and scaled so that, collectively, they match the segment's contribution to the index duration. To improve

tracking further, the manager may target other characteristics of each individual segment, such as convexity or credit quality. Of course, the more securities purchased in each segment, the more closely the portfolio will track the index.

This approach may work quite satisfactorily in homogeneous markets, such as U.S. governments or MBS. One very simple but effective approach to replicate governments requires just six securities. The index is partitioned into three market-specific maturity segments. The choice of these segments may reflect such market characteristics as auction cycles, maturity distribution, or refunding policies. Within each segment, the bonds are divided into two groups: one with durations above the segment's average and one below. One liquid bond is selected from each group. These two bonds are weighted in such a way that the total duration of the pair matches the duration of the segment they represent. The three pairs of bonds are then given appropriate weights to match the contributions of their segments to the index. This simple procedure ensures sufficiently close matching of the term-structure allocation that is the primary source of risk in government markets.

Stratified sampling also works well for the U.S. MBS market that has little idiosyncratic risk. For MBS replication it is usually sufficient to sample the index along just three dimensions: program (GNMA 30-year, conventional 30-year, and all 15-year), seasoning (seasoned, unseasoned), and price (premium, cusp, and discount).[16] Stratified sampling works less well for markets with much idiosyncratic risk (e.g., credit). Matching broad risk dimensions still leaves the proxy portfolio vulnerable to issuer-level risk because, by necessity, the proxy overweights each issuer relative to the benchmark. The important question of how to control the issuer-specific risk of a portfolio is discussed below.

Sometimes stratified sampling is the only available replication method—for example, in markets where multifactor risk models are not available. The actual techniques, while still based conceptually on sampling, may get quite sophisticated. First of all, special rules may be used for selecting individual bonds in each segment (e.g., starting from the largest issuer), as well as for setting the level of diversification in each segment (e.g., based on the segment's historical volatility). The sampling process may be performed within an optimization context. In this case, satisfying constraints is the main goal, with the objective function being a secondary consideration (yield, spread, or liquidity may be maximized, for example). The number of securities that end up in the replicating portfolio can be regulated by tightening or relaxing constraints.

The fundamental issues with replication techniques based on stratified sampling are the same as with the cell-based approach to analyzing risk. Matching some cells may be more critical than matching others because return volatility

16. Partitioning the MBS universe by price is essentially equivalent to partitioning by coupon. The advantage of using price is that the cutoff levels defining the boundaries do not change over time.

associated with these cells is higher. And sampling-based techniques ignore the all-important correlations among cells.

Replication with Cash Instruments: Tracking-Error Minimization

As mentioned earlier, multifactor risk models usually provide more accurate estimates of portfolio risk than sampling techniques that match the index risk parameters "naively," often ignoring historical variances and correlations of risk factors. Besides performing their primary function of measuring risk, multifactor models can be augmented with optimization capabilities. Given a set of securities representing the investable universe, a benchmark, and a set of constraints, an optimizer based on a multifactor model can pick a sample of bonds (a portfolio) with the minimum projected tracking error versus the benchmark. This may be done in one step, with the model being essentially a "black box" cranking out a solution. Or the model may allow the manager to step through the optimization one bond at a time, using his knowledge of relative value to select the best bond to buy from a list of candidates.

Tracking-error minimization has been applied successfully to construct replicating portfolios for broad benchmarks of the U.S. and global government and credit markets. This method also has proved very effective in replicating the Barclays Capital MBS Index.[17]

The realized performance of most actual replicating portfolios has been within the model-projected range. The level of tracking achieved by a replicating portfolio depends, of course, on the number of bonds it contains. As more bonds are added to the portfolio, tracking risk decreases. Exhibit 50–3 illustrates this tradeoff by showing how the projected monthly TEV of a corporate replicating portfolio versus the Barclays Capital U.S. Corporate Bond Index declines with the increase in the number of securities. At first, adding more securities to the portfolio reduces tracking error quickly, but gradually, the rate of decline slows. The explanation lies in the difference between systematic and idiosyncratic risk. As the plot shows, after the 60-bond level the systematic risk ceases to be a concern, reaching the almost negligible 2.6 bp/month for a 100-bond portfolio. Consequently, even relatively small portfolios can match the systematic risk exposures of a broad market index surprisingly well. The dominant type of risk for small portfolios is idiosyncratic. By the time the portfolio size reaches 100 bonds, the idiosyncratic risk contributes almost 100% of the total TEV and declines very slowly as more bonds are added to the proxy portfolio.

Multifactor risk models rely on historical experience over the calibration period. Such models may ignore a significant structural mismatch between the proxy and index that historically did not result in return volatility. There is always

17. Lev Dynkin, Vadim Konstantinovsky, and Bruce D. Phelps, "Tradable Proxy Portfolios for an MBS Index," *Journal of Fixed Income* 11:3 (2001), pp. 70–87.

EXHIBIT 50–3

Tracking Error Volatility versus the Barclays Capital U.S. Corporate Bond Index as a Function of the Number of Bonds in the Portfolio

Source: Barclays Capital

a chance that historical patterns will not hold over the next month, and that a mismatch will prove more consequential than the model thought. This is why stratified sampling analysis may be useful even in the presence of a powerful risk model. It may alert the portfolio manager to structural mismatches ignored by the model. In such cases, managers can use their judgment in deciding whether to rely on historical patterns.

Replication with Derivatives

Derivatives effectively reduce the number of dimensions in the portfolio management problem and simplify asset allocation shifts and deployment of cash inflows. Because of this, derivatives can be particularly useful in replicating the benchmark at the start-up phase, when diversified cash investments in tradable sizes are not easily available. Derivatives can also be used in portable alpha strategies, in which a manager's value-added from one strategy is "transported" into another strategy.

Treasury futures have been widely used as a duration-adjustment tool because of such advantages as no portfolio disruption, ease of establishing and unwinding positions, and low transaction costs. A derivatives version of the cell

matching technique using a mix of four Treasury futures contracts (2-, 5-, 10-, and bond) is effective in replicating the term structure exposure of any fixed-income index.[18] In this approach, an index is divided into four maturity (duration) cells, and the market value allocations and dollar durations of each cell are matched with a combination of cash and the appropriate futures contract. The cash can be invested in Treasury bills or other short-term instruments. For an added benefit, cash may be invested more aggressively into riskier and higher-yielding instruments such as commercial paper or floating rate notes. For investment funds with frequent and significant cash inflows and outflows, replication of benchmark returns with exchange-traded futures is often the preferred strategy. Similarly, a large asset allocation shift may be initiated with futures because of their liquidity and low trading costs. Less liquid cash assets can then be deployed gradually as opportunities arise.

While the term-structure exposure can be matched effectively with Treasury futures alone, spread risk needs to be hedged separately. The next level in derivatives replication techniques introduces Eurodollar futures and swaps to replicate indexes with credit-spread exposure. Replication strategies based on these instruments rely on the positive correlation between credit or MBS/ABS spreads on the one hand, and the Treasury-Eurodollar (TED) and swap spreads on the other. These strategies can successfully replicate credit and mortgage benchmarks.

A further enhancement introduces TBAs to replicate the mortgage component, and portfolio credit default swaps to replicate the credit component. TBAs offer two key advantages over mortgage pools in replication strategies: they are suitable for an unfunded strategy because no cash outlay is required; the back office aspects are much simpler because monthly interest payments and principal paydowns are avoided. Portfolio credit default swaps (CDX and iTraxx) are liquid instruments that investors can use to take a long or short position in credit. Credit yields can be broken down into two parts: the swap yield and a credit-spread to swaps. Accordingly, the exposure to movements in swap yields can be matched by using interest-rate swaps, and the exposure to movements in credit-spreads to swaps by using CDX. For example, such widely traded portfolio products as CDX.NA.IG represent baskets of equally-weighted CDS in 5- and 10-year maturities and can be useful in replicating credit indexes. TBAs and CDX swaps help reduce TEV for derivatives replication of the U.S. Aggregate Index.[19]

Finally, derivatives can be employed to replicate the broadest, multicurrency fixed income benchmarks. A global index presents investors with a portfolio management problem involving multiple yield curves and exchange rates, as

18. Lev Dynkin, Jay Hyman, and Peter Lindner, "Hedging and Replication of Fixed-Income Portfolios," *Journal of Fixed Income* 11:4 (2002), pp. 43–63.

19. Lev Dynkin, Anthony Gould, and Vadim Konstantinovsky, "Replicating Bond Indices with Liquid Derivatives," *Journal of Fixed Income* 15:4 (2006), pp. 7–19.

well as credit and issuer risk in several markets. As a matter of fact, this diversity of exposures makes global indexes particularly good candidates for replication with derivatives.

Typically, the single-market components of a global index are replicated separately and then combined into the resulting tracking portfolio. The greater number of risk dimensions in a global index provides better opportunities for diversification of the TEVs for each subcomponent of the index. For example, the tracking risk associated with replicating the U.S. MBS component is not likely to be highly correlated with the tracking risk in replicating the Euro-credit component. This will reduce the overall portfolio's TEV.

Investors have a wide range of choices for derivatives replication of a cash index. For example, an investor wishing to replicate the Barclays Capital U.S. Aggregate Index can choose among the following strategies: Treasury futures only; a blend of futures and interest rate swaps; futures, swaps and TBAs; futures, swaps, TBAs and CDX; swaps only; etc. In addition, it may, at times, be possible for an investor to find a counterparty with whom to enter into a total return swap on the index itself. With an index TRS, the investor agrees to receive the total return on the index from the counterparty in return for paying LIBOR plus a spread. The choice of a derivatives replication strategy will depend on the investor's sensitivity to monthly tracking errors versus cumulative tracking over time and the cost (both transactions cost and monitoring cost) of maintaining the replication strategy.

Some investors have little time or inclination to manage a large set of derivatives positions. To accommodate these investors a broker-dealer may offer a total return swap based on the total returns of a *basket* of derivatives, automatically rebalanced every month to minimize the expected tracking error to the underlying index. Because the replicating basket contains very liquid derivative instruments (e.g., futures and swaps), such total return bond replicating index swaps are inexpensive and liquid.

CONTROLLING ISSUER-SPECIFIC RISK IN THE PORTFOLIO

Credit crises like the one of 2008 usually compel portfolio managers to adopt a more disciplined approach to diversifying portfolio risk (although a few years of calm often erode this discipline). At the simplest level, managers try to avoid large exposures to single issuers and hold as many different issuers as practical. A more nuanced approach, described below, places stricter diversification requirements on lower-rated bonds, as event risk is more significant in lower credit strata, both in frequency and in loss severity.

Managers who do not pursue alpha via name selection may not buy cash securities at all, choosing alternative ways of getting credit sector exposure. Such "bondless" portfolios assume the net issuer risk of the benchmark. For sufficiently broad market indexes, such risk is usually much smaller than the issuer risk of a typical cash portfolio. Well-developed and liquid swap markets in several currencies provide

a viable means of getting credit exposure without acquiring actual securities and the associated exposure to their issuers. The credit derivatives markets, particularly credit default swaps, provide managers with even more flexibility in controlling credit exposures in their portfolios.

Sufficient Diversification in Credit Portfolios

The need to reduce issuer-specific risk by diversification is obvious to any credit manager. Very often, though, the diversification is pursued in a simplistic way; for example, by setting issuer or security allocation limits without regard for credit quality. On the other hand, diversification should not be viewed as an unqualified benefit because there is a downside to it as well, from increased transaction costs as more bonds are purchased, to the dilution of the value of credit research as bonds with less perceived upside are added solely to increase diversification. This issue has been addressed in a study of optimal diversification levels in credit portfolios.[20] A simple model of downgrade risk was proposed, based on the observed historical underperformance of downgraded bonds and transition probabilities published by rating agencies.

The study answers the following question: for a portfolio of a given number of bonds, how many bonds of each credit quality should be held to achieve the lowest tracking error due to downgrade risk? The optimal allocations are skewed in their diversification levels (i.e., in maximum allowed position sizes) across qualities. For the study period from August 1988 through September 2010, the optimal ratio of position sizes for the three major investment-grade credit categories was found to be roughly 3 : 1.5 : 1. In other words, the optimal position size in Baa-rated bonds, for example, was one third the position size of Aaa/Aa-rated bonds. Compared with earlier periods, this ratio is not very skewed because in the credit crisis of 2008, higher quality bonds, primarily A- and Aa-rated financials, experienced significant turmoil.[21] The ratio reflects only one type of idiosyncratic risk—the risk of a downgrade. Of course, issuer-specific events may be quite significant but not accompanied by a downgrade. Indeed, this type of volatility usually dominates in the higher-quality segment of the market. When one takes into account the spread volatility not caused by rating transitions, the position size ratio becomes less skewed, but still indicates smaller position limits in lower qualities.

Clearly, these ratios should never be used as a literal directive when structuring credit portfolios. They depend heavily on the methodology and the historical period covered by the study. Yet the very clear and enduring lesson is that to lower the overall issuer-specific risk, it is most important to diversify exposures to lower-rated issuers. This conclusion has implications for plan

20. For the original study, see Lev Dynkin, Jay Hyman, and Vadim Konstantinovsky, "Sufficient Diversification in Credit Portfolios," *Journal of Portfolio Management* 29 (2002), pp. 89–114.

21. Over the period of 1988–2002 for example, the ratio was a more dramatic 10 : 3 : 1.

sponsors as well: portfolio guidelines that establish maximum position limits to force diversification should not do so evenly across credit qualities.

To counterbalance the desire to reduce event risk as much as possible, managers should carefully consider the costs associated with increasing the number of issuers in a portfolio. First, transaction costs increase as the portfolio transacts more and in smaller amounts. Second, there is the overhead of monitoring a larger number of issuers. Finally, as managers push to add issuers for diversification's sake, they will be forced to add issuers less highly regarded by their credit analysts. Consequently, the optimal level of diversification is determined by the tradeoff between the reduction of issuer-specific risk and the dilution of outperformance. The development of quantitative models that pinpoint this optimal level is possible but not trivial. Such models need to consider both the marginal cost and the marginal value of credit research, as well as the portfolio's size and many other factors.

Swaps as a Total-Return Investment

Interest rate swaps traditionally are used as a risk-management tool to adjust portfolios' term structure and spread exposures. However, swaps have received attention as a total-return investment.

Changes in the credit risk premium influence both swap and credit-spreads. Expectations of significant changes in the future Treasury supply, for example, as well as "specialness" of individual Treasury securities affect the spreads over Treasuries of both swaps and other spread product. As discussed earlier, Barclays Capital publishes interest rate swap indexes that help investors analyze and use swaps as just another asset class, complete with pricing, returns, and analytics.

As mentioned earlier, among the published swap indexes are so-called mirror indexes that match the term-structure (i.e., key rates) exposure of various popular fixed income benchmarks. Despite monthly tracking volatility, over the long period from August 1992 through October 2010, the cash components of the Barclays Capital Aggregate Index performed roughly in line with their mirror swap indexes, as interest-rate exposures are the key determinant of fixed income asset performance. However, during periods of market stress, swaps tend to outperform. In 2008, for example, every single subindex of the Aggregate Index underperformed its mirror swap index by a wide margin. Although that was a time of extreme market conditions, and there were historical periods when swaps underperformed, it is clear that swaps have a performance potential that investors should consider along with other spread asset classes.

Swap spreads usually are aligned with credit-spreads, although certain factors can cause them to diverge. For example, in a steep yield-curve environment, swapping activity by corporations intensifies, leading to the tightening of swap spreads unaccompanied by the corresponding tightening of credit-spreads. Although such factors weaken the case for swaps as a credit proxy, they promote the role of swaps as a means to diversify systematic risk in total return portfolios.

EXHIBIT 50–4

Correlation Matrix: Excess Returns over Treasuries, July 1992–October 2010

	Aggregate	Credit	Agency	MBS	ABS	5-Yr Swaps
Aggregate	1	0.92	0.71	0.66	0.72	0.48
Credit		1	0.58	0.39	0.71	0.40
Agency			1	0.55	0.34	0.69
MBS				1	0.39	0.43
ABS					1	0.20
5-Yr Swaps						1

Source: Barclays Capital

Exhibit 50–4 shows that for the period from July 1992 through October 2010, five-year swaps had a noticeably lower excess return correlation with the Barclays Capital Aggregate Index than did any of the index's four main spread components. The low excess return correlation implies that adding five-year swaps to a diversified portfolio of agencies, credit, mortgage-backed, and asset-backed securities may reduce risk.

The treatment of swaps as a total-return investment should be considered from a tactical as well as a strategic asset allocation perspective. The outperformance and diversification properties that swaps have demonstrated over the recent years make them a valuable tool for total-return portfolio managers.

Credit Default Swaps as Protection against Issuer Risk

Credit default swaps (CDS) have a place in many portfolios. CDS can be used to hedge existing credit exposures in the portfolio and to create new exposures that could not be created otherwise; for example, taking short positions to express a negative view. A conventional cash corporate bond bundles together exposures to interest rates, swap spread, credit-spread (over swaps), and possibly currency risk as well. CDS allow investors to pick from this bundle of exposures only the desired one. With CDS, investors can separate their views on a particular credit (issuer) from views on the market segment to which that issuer belongs.

Besides their primary function of hedging the default risk of particular issuers, CDS are used in a number of other ways. Some investors place bets on the "CDS-cash basis," that is, the spread between a CDS and corporate debt of the same issuer, or express relative views on two issuers. Finally, CDS are often more liquid than the underlying corporate bonds, providing an easier and cheaper way to get a desired exposure.

QUANTITATIVE METHODS FOR PORTFOLIO OPTIMIZATION

Optimization has been an important part of investment practice since the introduction of mean-variance analysis more than 50 years ago. The asset management problem lends itself quite naturally to optimization techniques. Almost always, it is a multi-variable, multi-constraint task with a well-defined objective. A portfolio of financial assets has two essential characteristics: investment return and risk (i.e., uncertainty about the magnitude of return). Therefore, the countless optimization methods and tools developed over the past decades target one of these two characteristics while controlling the other.

Historically, the usual objective function of portfolio optimization has been to maximize expected return relative to risk. This requires upfront estimates for expected returns of every asset considered in the optimization. As discussed below, historical data, whether long-term or recent, are poor predictors of future performance. Analysts' forecasts are imperfect as well. This section examines two examples of optimization techniques that do not rely on explicit predictions of asset performance.

Optimal Risk Budgeting Based on Skill

The managing of large, multi-asset portfolios is usually a collective effort. Various managers, analysts, or teams form opinions relevant to particular segments of the overall portfolio. Then all these opinions are considered by some central decision-making authority. This may be a committee of the very same portfolio managers responsible for individual portfolio segments, often supervised by a chief investment officer. Multiple recommendations have to be reconciled: "go long duration," "overweight the 10-year segment of the curve," "underweight industrials," "buy current coupon mortgages," etc. How can the decision makers establish the magnitudes of exposures along all these dimensions? They need to consider the interaction among all the intended exposures and the resulting overall portfolio risk. But first and foremost, they estimate (explicitly or implicitly) the degree of confidence in each particular recommendation, which depends on the perceived skill of those who made that recommendation.

The manager's skill is a critical factor that largely determines portfolio performance. While this is obvious, oddly enough, the notion of skill is rarely used formally when allocating portfolio risk or projecting expected outperformance. Even more surprisingly, skill rarely is measured in any disciplined way.

Several studies have examined the role of skill in the historical performance of various investment strategies.[22] These skill-based historical simulations produced an interesting conclusion. The information ratios of very diverse strategies

22. *Quantitative Management of Bond Portfolios*, Chapters 24 and 25.

were very similar for a given skill level. Apparently, when performance is measured on a risk-adjusted basis, the particular nature of an investment strategy plays a minor role. Performance is essentially determined by the skill and dimensionality (the number of independent decisions) of the strategy.

The empirical results confirm the "Fundamental Law of Active Management" defined by Grinold and Kahn.[23] This law states that the information ratio of an investment strategy is determined by two factors: the "information coefficient" based on correlation between predictions and realizations (and closely related to the probability-based skill) and "breadth" or the number of independent decisions made by the strategy.

Because the information ratio is outperformance (alpha) divided by risk (tracking-error volatility), the law can be expressed slightly differently by stating that a strategy's alpha is proportional to risk, skill, and the number of independent decisions.

This idea has fundamental implications for portfolio optimization. Asset managers traditionally have used the mean-variance approach to find the optimal asset allocation that maximizes expected outperformance, or alpha, for a given level of risk (or minimizes risk for a given alpha). The Achilles' heel of this approach is the expected returns of asset classes (or strategies) used in the optimization.

The Barclays Capital proprietary risk-budgeting methodology—*ORBS* (*O*ptimal *R*isk *B*udgeting with *S*kill)—relies on skill levels, breadth, and directional views to allocate the total risk budget among macro strategies to maximize portfolio alpha. Skill at timing a given strategy is defined as a percentage of directionally correct forecasts for this strategy minus the percentage of directionally wrong forecasts. The risk allocated to an individual strategy is then translated into the size of an active position that corresponds to that risk. At the core of this risk-budgeting methodology is a covariance matrix of returns for the asset classes underlying all considered strategies. This framework is very flexible and can be applied to essentially any set of asset classes and investment strategies with any number of different constraints.

Asset Allocation for Buy-and-Hold Investors

A corporate bond provides investors with a relatively small spread over Treasuries during its lifetime in compensation for the risk of a large, albeit unlikely, loss from default. While default risk is issuer-specific and can be reduced via diversification, correlation of defaults among issuers makes it impossible to eliminate it completely. This asymmetric risk/return profile of credit investing corresponds most closely with the considerations of a long-term investor who intends to hold bonds to maturity. In contrast, most total-return investors have a much shorter time frame and perceive a very different, less asymmetric risk/return profile.

23. Richard Grinold and Ronald N. Kahn, *Active Portfolio Management* (New York: McGraw-Hill, 1999).

For a total-return investor, the dominant risks are spread volatility (essentially symmetric) and possible loss of liquidity. At least in investment-grade markets, credit-quality deterioration typically occurs gradually, so the primary risk for a total-return investor is not default but rather downgrade (and the accompanying spread widening).

This difference in perspective has major implications for buy-and-hold investors. The spreads observed in the market result from interactions among all market participants, many of whom are total-return investors. If these investors expect high short-term spread volatility or liquidity risk, they can drive spreads much wider than would be justified by long-term default risk alone. This action can work to the benefit of long-term credit investors unaffected by short-term risks.

The asymmetric nature of the risk/return profile for long-term investors should be reflected in their asset allocation process. The most common approach to asset allocation, mean-variance optimization, generally is not suitable for buy-and-hold investors. In mean-variance optimization, risk is represented by the standard deviation of asset returns, which implies a symmetric distribution. For very asymmetric return profiles, standard deviation is not a particularly helpful measure of risk. In fact, no single measure of risk is universally appropriate for dealing with extreme, or "tail," events. The treatment of this "tail risk" must be customized to the needs and risk tolerance of each investor. One approach to asset allocation focuses on the downside risk, that is, the part of the return distribution that is below a certain minimum required return. This approach, though, requires a fuller description of the return distribution; the mean and standard deviation are not sufficient.

The central problem in the buy-and-hold asset allocation process is the fundamental tradeoff between current credit-spreads and expected horizon defaults. When is credit "cheap" from a buy-and-hold perspective? The answer depends on the level of default risk in the portfolio. To what extent can the default risk be reduced by issuer diversification, that is, how many issuers should a portfolio contain to limit default loss to a certain threshold with a given level of confidence? Or what allocation among different credit qualities will maximize spread within a given limit of the tail risk? Sophisticated quantitative models and techniques have been developed to address these matters.[24] There is an extensive body of research literature dealing with modeling default risk and particularly with default correlation.

TOOLS FOR QUANTITATIVE PORTFOLIO MANAGEMENT

The challenge for building a good quantitative portfolio-level system comes from the simultaneous need for broad asset class coverage and consistency of

24. *Quantitative Management of Bond Portfolios*, Chapter 16.

analytics across all asset classes. Specialized systems usually offer advanced analytics for specific asset classes. The objective for a portfolio system is to treat a wide range of asset classes within a single consistent framework without giving up too much accuracy.

At the foundation of a powerful analytical suite are basic security-level analytics, such as cash-flow projection, spread-to-price conversion, or duration calculation. The word *basic* belies the enormous complexity of this task. The variety of financial assets available to investors is ever-expanding and necessitates powerful underlying yield-curve, mortgage-prepayment, option-pricing, and volatility models.

Built on security pricing models is a broad set of portfolio-level analytics, that is, portfolio management tools that help managers analyze portfolio risk exposures, estimate the effect of various changes to portfolio structure, construct optimal portfolios, and attribute achieved performance. An important part of this analytical suite is a multifactor risk model. When such a model is enhanced with optimization capabilities, it becomes a powerful tool for portfolio construction.

A useful complement for history-based risk modeling is flexible scenario analysis. An advanced scenario analysis engine is able to expand a few user-provided inputs into a complete set of maximum-likelihood scenarios for all relevant risk factors. A flexible performance attribution model is another essential component of the analytical suite. Various portfolio optimization tools, such as the risk-budgeting framework described earlier, complete the picture. Each of these building blocks requires sophisticated financial modeling and computer implementation effort. The added challenge is to ensure consistency among all these various tools. The conclusions a manager derives from the risk model should not contradict those from scenario analysis. The ex-post return analysis should attribute the achieved outperformance to the risk exposures highlighted in the ex-ante risk analysis.

KEY POINTS

- Portfolio management entails two essential functions: forming market views at a macro and/or security level and optimally implementing those views in the portfolio.
- Portfolio managers usually focus on the first task. Success in uncovering relative value by market timing, sector, or name selection requires experience and intuition and is usually equated with portfolio management talent.
- Constructing actual portfolios that reflect the desired views is just as vital for ultimate performance. It is this task that is greatly aided by quantitative methods and benefits from the methodologies, tools, and studies described in this chapter.

- Quantitative approaches can add value at each step of the portfolio management process: selection, customization and replication of benchmarks; construction and optimization of benchmarked portfolios; risk analysis; performance attribution; and empirical support of investment decisions.

CHAPTER
FIFTY-ONE

GLOBAL CREDIT BOND PORTFOLIO MANAGEMENT

JACK MALVEY, CFA
Chief Global Markets Strategist
BNY Mellon Asset Management

Corporate bonds are the most demanding and fascinating subset of the global debt capital markets. The label, *corporate,* understates the scope of this burgeoning asset class. As commonly traded and administered within the context of an overall debt portfolio, the "corporate asset class" actually encompasses much more than pure corporate entities. Instead of the title, *corporate asset class,* this segment of the global bond market really should be classified as the *credit asset class,* including non-agency mortgage-backed securities (MBS), commercial mortgage-backed securities (CMBS), and asset-backed securities (ABS). Sovereigns and government-controlled entities with foreign currency debt issues thought to have more credit risk than the national government also should be included. In keeping with conventional practice in the debt market, however, the application of the term *credit asset class* in this chapter will pertain only to corporate bonds, sovereigns, and government-controlled entities.

From six continents, thousands of organizations (corporations, government agencies, projects, and structured pools of debt securities) with different credit "stories" have sold debt to sustain their operations and to finance their expansion. These borrowers use dozens of different types of debt instruments (first mortgage bonds, debentures, equipment trust certificates, subordinated debentures, medium-term notes, floating-rate notes, private placements, preferred stock) in multiple currencies (dollars, yen, euros, sterling, Swiss francs, reals, renminbi) from maturities ranging from one year to even a thousand years. Sometimes, these debt structures carry embedded options, which may allow for full or partial redemption prior to maturity at the option of either the borrower or the investor. Sometimes, the coupon payment floats with short-term interest rates or resets to a higher rate after a fixed interval or a credit-rating change.

Parts of this chapter are adapted from "Relative-Value Methodologies for Global Credit Bond Portfolio Management," Chapter 5 in Frank J. Fabozzi (ed.), *Fixed Income Readings for the Chartered Financial Analyst Program* (New Hope, PA: Frank J. Fabozzi Associates, 2004).

EXHIBIT 51–1

Rolling 5-year Excess Return of U.S Investment-Grade Credit: 1988–2010

Investors buy credit assets because of the presumption of higher long-term returns despite the assumption of credit risk. Except immediately prior and during recessions, credit products usually outperform local government bond benchmarks like U.S. Treasury securities and other higher-quality "spread sectors" such as U.S. agency securities, mortgage-backed securities, and asset-backed securities. In the 38-year period since the beginning of the Barclays/Lehman indexes (1973–2010), U.S. investment-grade credit outperformed U.S. Treasuries by 29 basis points (bp) per year on average (8.31% versus 8.02%) as shown in Exhibit 51–1.[1] As usual, an average masks the true daily, weekly, monthly, and annual volatility of credit assets relative performance. Looking at the rolling five-year excess returns of U.S. investment-grade credit from 1988 through 2010 in Exhibit 51–1, there have been extended periods of generous (1991–1995) and disappointing returns (2004–2008) for credit assets.

Global credit portfolio management presents a complex challenge. Each day hundreds of credit portfolio managers face thousands of choices in the primary (new issue) and secondary markets. In addition to tracking primary and secondary flows, investors have to keep tabs on ever-varying issuer fundamentals, creditworthiness, acquisitions, earnings, ratings, and prices cast in multiple gauges (bond price, nominal spread, interest-rate swap spread, and credit default swap spread). The task of global credit portfolio management is to process all this rapidly changing information about the credit markets (issuers, issues, dealers, and competing managers) and construct the portfolio with the best return for a

given risk tolerance. This discipline combines the qualitative tools of equity analysis with the quantitative precision of debt analysis.

Exhibit 51–2 illustrates the magnitude of this information-processing challenge. From a set of 5,000 different issuers, investors can assemble 4 × 10 (55) different combinations of 20-bond portfolios. The number of potential portfolio combinations of 20 bonds expands to the infinity neighborhood with the inclusion of additional variables such as rating (20 choices), issues (100,000), and currencies (at least 20). Incredibly, the number of potential combinations of this 20 bond credit portfolio exceeds the neutrons in the known universe. In turn, this begs the question of whether credit portfolio "optimization" is truly achievable given the current state of technology. Although perfect optimization may prove elusive, the optimization goal remains a worthy pursuit for asset managers.

Despite this apparent limitation on the perfection of credit portfolio optimization, broad demand exists for credit debt. Investors in credit debt consist of individuals in the pursuit of incremental yields above government bonds, central banks aiming to extract a higher yield and return on their considerable holdings of fixed income assets, commercial banks arbitraging the difference between the greater yields on floating-rate notes and their lower cost of funding, mutual funds attempting to maximize both yield and total return, insurers and state pension funds seeking to fund their projected long-term liabilities, "pure" total-return maximizers competing against each other on a monthly, quarterly, and annual basis to satisfy their clients (public or private pension fund plan sponsors) or risk their loss, and hedge funds staking out leveraged long or short positions in credits

EXHIBIT 51–3

Global Credit Sector Asset Allocation Methodology

with short-term potential for major price and spread movements. Portfolio investment choices are driven also by the existing security population of the credit market (sector, issuer, structure, and currency) and often the need to constrain tracking error deviations from broad corporate indices, by the psychology of portfolio managers (overall risk tolerance, shortfall risk aversion, and internal politics of the investment-management institution), and the state of market liquidity.

Borrowers and investors intersect mainly through dealers in both the classic telephone form and increasingly through "e-market techniques" such as websites and e-mails. Each day a few dozen credit bond dealers convey information about secondary positions and new issue offerings from any of the thousands of corporate borrowers to the hundreds of corporate bond portfolio managers. Through their investment banking and syndicate operations, dealers also advise issuers on when and how to sell new debt. Through their debt research, sales, and trading arms, dealers relay investment recommendations to portfolio managers.

As shown in Exhibit 51–3, the task of global credit bond portfolio management is to process rapidly changing information about the credit bond market (cash and derivative prices, industry and issuers' fundamentals, ratings, issuance, demand, dealer market-making, and competing asset managers) and construct a portfolio with the best expected return for a given risk tolerance.

CREDIT RELATIVE-VALUE ANALYSIS

Credit portfolio management represents a major subset of the multi-asset global portfolio management process illustrated in Exhibit 51–4. After setting the currency

EXHIBIT 51–4

Fixed Income Portfolio Management Process

allocation (in this case, dollars were selected for illustration convenience) and distribution among key debt asset classes (Treasuries, agencies, asset-backed securities, commercial mortgage-backed securities, and mortgage-backed securities), bond managers are still left with a lengthy list of questions to construct an optimal credit portfolio. Some examples are:

- What stages are the global and local business cycles (peak, descending to recession, recession, ascending to peak)?
- How are overall capital market liquidity conditions and dealer receptiveness to trading?
- Will structural changes in broad market themes, geopolitical risk, regulation, rating agency philosophy, and portfolio management methodology affect valuations?
- Should U.S. investors add U.S. dollar–denominated bonds of non-U.S. issuers?
- Should global credit market investors in 2011 bank on ultimate fiscal recovery of key European sovereigns (Greece, Ireland, Portugal, Spain, Italy) or wait for more information?
- Should central banks and Sovereign Wealth Funds add high-quality euro-denominated corporate bonds or high-quality emerging market sovereigns to their reserve holdings?
- Should LIBOR-funded London-based portfolio managers buy fixed-rate U.S. industrial paper and swap into floating-rate notes?

- Should Japanese mutual funds own euro-denominated telecommunications debt swapped back into dollars or yen using currency swaps?
- Should U.S. insurers buy perpetual floaters (i.e., floaters without a maturity date) issued by British banks and swap back into fixed-rate coupons in dollars using a currency/interest rate swap?
- When should investors reduce their allocation to the credit sector and increase allocation to governments, pursue a "strategic upgrade trade" (sell Baa/BBBs and buy higher-rated Aa/AA credit debt), rotate from industrials into utilities and/or financial institutions, switch from consumer cyclicals to noncyclicals, overweight airlines and underweight telephones, or deploy a credit derivative (e.g., short the high-yield index or reduce a large exposure to a single issuer by selling an issuer-specific credit default swap) to hedge their portfolios?

To respond to such questions, managers need to begin with an analytical framework (relative-value analysis) and to develop a strategic outlook for the global credit markets.

Relative Value

Economists have long debated the concept and measurement of "value." But fixed income practitioners, perhaps because of the daily pragmatism enforced by the markets, have developed a consensus about the definition of value. In the bond market, *relative value* refers to the ranking of fixed income investments by geographic regions, sectors, structures (i.e., fixed versus floating rate), issuers, and issues in terms of their expected performance over some future period of time (horizon).

For a day trader, relative value may carry a maximum horizon of a few minutes. For a dealer, relative value may extend from a few days to a few months. For a total-return investor, the relative-value horizon typically runs from one to three months. For a large insurer, plan sponsor, and sovereign wealth fund, relative value usually spans a multiyear horizon. Accordingly, *relative-value analysis* refers to the methodologies used to generate such rankings of expected returns.

Classic Relative-Value Analysis

There are two basic approaches to global credit bond portfolio management—*top-down approach* and *bottom-up approach*. The top-down approach focuses on high-level allocations among broadly defined credit asset classes. The goal of top-down research is to form views on large-scale secular economic and industry developments like geopolitical risk, demographics, climate change, energy, global monetary and fiscal policies, global trade and capital flow imbalances, and plan

sponsor investment philosophy. These views then drive asset allocation decisions (overweight certain sectors, underweight others). The bottom-up approach seeks to identify individual issuers and issues that will outperform their peer groups. Managers follow this approach hoping to outperform their benchmark owing to superior security selection while maintaining mainly neutral weightings to the various sectors in the benchmark.

Classic relative-value analysis is a dialectic process combining the best of top-down and bottom-up approaches as shown in Exhibit 51–5. This process blends the macro input of chief investment officers, strategists, economists, and portfolio managers with the micro input of credit analysts, quantitative analysts, and portfolio managers. The goal of this methodology is to pick the sectors with the most potential upside, populate these favored sectors with the best representative issuers, and select the structures of the designated issuers at the yield-curve points that match the investor's overall duration target and perspective on the Treasury benchmark yield-curve.

For many credit investors, the use of classic relative-value analysis usually leads to portfolio management success. Although sector, issuer, and structural analyses remain the core of superior relative-value analysis, the increased availability of information and technology has transformed the analytical process into a complex discipline. Credit portfolio managers have far more data than ever on the total returns of sectors, issuers, and structures; quantity and composition of new-issue flows; investor product demand; aggregate credit-quality movements; multiple sources of fundamental and quantitative credit analyses on individual issuers; and yield-spread data to assist them in their relative-value analysis.

Relative-Value Methodologies

The main methodologies for credit relative-value maximization are

- Total-return analysis
- Primary market analysis
- Liquidity and trading analysis
- Secondary trading rationales and constraints analysis
- Spread analysis
- Structure analysis
- Credit-curve analysis
- Credit analysis
- Asset allocation/sector analysis

In the sections that follow, we discuss each of these methodologies.

EXHIBIT 51–5

Credit-Sector Portfolio Management Process: Classic, Dialectic Relative-Value Analysis

TOTAL-RETURN ANALYSIS

The goal of global credit portfolio management for most investors is to optimize the risk-adjusted total return of their credit portfolio. The best place to start is naturally total-return analysis. Accordingly, credit relative-value analysis begins with a detailed dissection of past returns and a projection of expected returns. For the entire asset class and major contributing subsectors (such as banks, utilities, natural gas pipelines, sovereigns, Baa/BBBs, etc.), how have returns been generated? How much is attributed to credit-spread movements, sharp changes in the fundamental fortunes of key issuers, and yield-curve dynamics? If there are macro determinants of credit returns (the total return of the credit asset class), then credit markets may display regular patterns. For instance, the macroeconomic cycle is the major driver of overall credit-spreads. With the approach of and during recessions, the escalation of default risk widens spreads (which are risk premiums over underlying, presumably default-free government securities—or swaps) and reduces credit returns relative to Treasuries. Conversely, economic prosperity reduces bankruptcies and enhances overall credit fundamentals of most issuers. Economic growth usually leads to tighter credit-spreads and boosts credit returns relative to Treasuries. For brief intervals, noncyclical technical factors can offset fundamentals. For example, the inversion of the U.S. Treasury yield-curve in 2000 actually led to wider credit-spreads and credit underperformance despite solid global economic growth and corporate profitability.

Thanks to the development of total-return indexes for credit debt (databases of prices, spreads, issuer, and structure composition), analyses of monthly, annual, and multiyear total returns have uncovered numerous high-frequency patterns (i.e., large issue versus small issue performance variation, seasonality, election-cycle effects, and government benchmark auction effects) in the global credit market. Although they do not always recur, an awareness and understanding of these regular patterns is essential to optimizing portfolio performance.

PRIMARY MARKET ANALYSIS

The analysis of primary markets centers on new-issue supply and demand. Supply is often a misunderstood factor in tactical relative-value analysis. Prospective new supply induces many traders, analysts, and investors to advocate a defensive stance toward the overall credit market as well as toward individual sectors and issuers. Yet the premise, "supply will hurt spreads," which may apply to an individual issuer, does not generally hold up for the entire credit market. Credit-spreads are governed by many factors; supply, although important, represents one of many determinants of spreads. During most years, increases in issuance (most notably during the first quarter of each year) are associated with market-spread contraction and strong relative returns for credit debt. In contrast, sharp supply declines are accompanied frequently by spread expansion and a major fall in both relative and absolute returns for credit securities. For example,

this counterintuitive effect was most noticeable during August–October 1998 (Russian devaluation/default and Long-Term Capital Management implosion) and August–December 2008 (fall of Lehman Brothers and onset of global financial panic) when new issuance nearly disappeared in the face of a substantial increase in credit-spreads.

In the investment-grade credit market, heavy supply is often associated with spread compression and boosts relative returns for credit assets as new primary valuations validate and enhance secondary valuations. When primary origination declines sharply, secondary traders lose reinforcement from the primary market and tend to reduce their bid spreads. Contrary to the normal supply–price relationship, relative credit returns often perform best during periods of heavy supply. For example, 2009–2010 will be recalled for both the then all-time record for new credit origination and the best relative performance for global credit securities in decades.

The Effect of Market-Structure Dynamics

Given their immediate focus on the deals of the day and week, portfolio managers often overlook short- and long-term market-structure dynamics in making portfolio decisions. Because the pace of change in market structure is often gradual, market dynamics have less effect on short-term tactical investment decision making than on long-term strategy.

The composition of the global credit bond market shifted markedly over the last third of the twentieth century and continues in the twenty-first century. For example, medium-term notes (MTNs) dominated issuance in the front end of the credit yield-curve (1–7 year maturities) since the 1980s. Structured notes and swap products heralded the introduction of derivative instruments into the mainstream of the credit market in the 1990s. The high-yield corporate sector became a widely accepted asset class in the 1980s, with emerging market debt following in the 1990s. Global origination became more popular since the early 1990s for U.S. government agencies, supranationals (e.g., World Bank), sovereigns, and large corporate borrowers.

Although the ascent of derivatives and high-yield instruments stood out during the 1990s, the quickening march toward full credit market globalization was the most important structural trend. The rapid development of the Eurobond market since 1975, the introduction of many non-U.S. issuers into the dollar markets during the 1990s, and the birth of the euro on January 1, 1999 have led to the proliferation of truly transnational credit portfolios. The accelerating expansion of local-currency denominated debt origination, especially from Brazil, Russia, India, and China (the so-called BRICs), likely will be recalled as the most prominent evolutionary feature of early twenty-first century global credit markets.

These long-term structural changes in the composition of the global credit asset class arise owing to the desire of issuers to minimize funding costs under different yield-curves and yield spreads, as well as the needs of both active and

asset/liability bond managers to satisfy their risk and return objectives. Portfolio managers will adapt their portfolios either in anticipation of or in reaction to these structural changes across the global credit markets.

The Effect of Product Structure

Partially offsetting this proliferation of issuers since the mid 1990s, the global credit market has become structurally more homogeneous. Specifically, bullet and intermediate-maturity structures have come to dominate the credit market. A *bullet maturity* means that the issue is not callable, putable, or sinkable prior to its scheduled final maturity. The trend toward bullet securities does not pertain to the high-yield market, in which callables remain the structure of choice. With the hope of credit-quality improvement, many high-yield issuers expect to refinance prior to maturity at lower rates.

There are three strategic portfolio implications for this structural evolution. First, the dominance of bullet structures translates into scarcity value for structures with embedded call and put features. That is, credit securities with embedded options have become rare and therefore demand a premium price. Typically, this premium (price) is not captured by option-valuation models. Yet, this "scarcity value" should be considered by managers in relative-value analysis of credit bonds.

Second, bonds with maturities beyond 20 years are a small share of outstanding credit debt. This shift reduced the effective duration of the credit asset class and cut aggregate sensitivity to interest-rate risk. For asset/liability managers with long-time horizons, this shift of the maturity distribution suggests a rise in the value of long-credit debt and helps to explain the warm reception afforded, initially at least, to the handful of new offerings of issues with 100-year maturities in the early and mid 1990s as well as 2010.

Third, the use of credit derivatives has skyrocketed since the early 1990s. The rapid maturation of the credit derivative market has led investors and issuers to develop new strategies to match desired exposures to credit sectors, issuers, and structures. In particular, many high-frequency traders (dealer desks, hedge funds, and active total return managers) prefer to execute their long and short credit positions in highly liquid portions of the CDS market rather than in conventional cash credit securities.

LIQUIDITY AND TRADING ANALYSIS

Short- and long-term liquidity needs influence portfolio management decisions. Citing lower expected liquidity, some investors are reluctant to purchase certain types of issues such as small-sized issues (less than $1 billion), private placements, MTNs, and nonlocal corporate issuers. Other investors gladly exchange a potential liquidity disadvantage for incremental yield. For investment-grade investors with even a medium-term horizon of more than six months, these liquidity concerns often are exaggerated.

The liquidity of credit debt changes over time. Specifically, liquidity varies with the economic cycle, credit cycle, shape of the yield-curve, supply, and the season. As in all markets, unknown shocks, such as a surprise wave of defaults or an eruption of geopolitical risk as in the immediate wake of 9/11, can reduce credit debt liquidity as investors become unwilling to purchase new issues at any spread and dealers become reluctant to position secondary issues except at very wide spreads. In reality, these transitory bouts of illiquidity mask an underlying trend toward heightened liquidity across the global credit asset class. With a gentle push from regulators, the global credit asset class is well along in converting from its historic "over-the-counter" domain to a fully transparent, equity/U.S. Treasury–style marketplace. In the late 1990s, new technology led to creating ECNs (electronic communication networks), essentially electronic trading exchanges. And in July 2002, the U.S.-based regulatory agency, FINRA, introduced the Trade Reporting and Compliance Engine (TRACE) to track publicly all institutional-sized trades of credit securities. In turn, credit bid/ask spreads generally have shifted lower for very large, well-known credit issues. This powerful combination of technological innovation and competition promises the rapid development of an even more liquid and efficient global credit market during the twenty-first century.

SECONDARY TRADE RATIONALES

Capital market expectations constantly change. Recessions may arrive sooner rather than later. The yield-curve may steepen rather than flatten in anticipation of monetary policy adjustments. The auto and paper cycles may be moving down from their peaks. Higher oil and natural gas prices may enhance the credit quality of the energy sector. An industrial may have announced a large debt-financed acquisition, earning an immediate ratings rebuke from the rating agencies. A major firm may plan to repurchase 15% of its outstanding common stock (great for shareholders but leading to higher financial leverage for debt holders). In response to such daily information flows, portfolio managers amend their holdings. To understand trading flows and the real dynamics of the credit market, investors should consider the most common rationales of whether to trade and not to trade.

Popular Reasons for Trading

There are dozens of rationales to execute secondary trades when pursuing portfolio optimization. Several of the most popular are discussed below.

Yield-Spread Pickup Trades

Yield-spread pickup trades represent the most common secondary transactions across all sectors of the global credit market. Historically, at least half of all secondary swaps reflect investor intentions to add additional yield within the overall

duration and credit-quality constraints of a portfolio. If five-year Aa2/AA+ GE Capital paper trades at 114 basis points, 79 basis points less than three-year A2/A Bank of America, some investors will determine the rating and maturity differential irrelevant and purchase the Bank of America bond and sell the GE Capital (an issue swap) for a spread gain of 79 basis points per annum.

This "yield-first psychology" reflects the institutional yield need of long-term asset/liability managers (plan sponsors and insurers). Despite the passage of more than three decades, this investor bias toward yield maximization also may be a methodological relic left over from the era prior to the introduction and market acceptance of total-return indexes in the early 1970s.

Credit-Upside Trades

Credit-upside trades take place when the debt asset manager expects an upgrade in an issuer's credit quality that is not already reflected in the current market yield spread. In the illustration of the GE Capital and Bank of America trade described above, some investors may swap based on their view of potential credit-quality improvement for Bank of America. Obviously, such trades rely on the credit analysis skills of the investment management team. Moreover, the manager must be able to identify a potential upgrade before the market; otherwise, the spread for the upgrade candidate will already exhibit the benefits of a credit upgrade.

Credit-upside trades are particularly popular in the crossover sector—securities with ratings between Ba2/BB and Baa3/BBB– by two major rating agencies. In this case, the portfolio manager is expressing an expectation that an issue of the highest speculative grade rating (Ba1/BB+) has sufficiently positive credit fundamentals to be upgraded to investment-grade (i.e., Baa3/BBB–). If this upgrade occurs, then not only would the issue's spread narrow based on the credit improvement (with an accompanying increase in total return, all else equal), but the issue also would benefit from improved liquidity because managers prohibited from buying high-yield bonds could then purchase that issue. Further, the manager would expect an improvement in the portfolio's overall risk profile.

Credit-Defense Trades

Credit-defense trades become more popular as geopolitical and economic uncertainty increase. Secular sector changes also often generate uncertainties and induce defensive positioning by investors. In anticipating greater competition in the mid 1990s, some investors reduced their portfolio exposures to sectors such as electric utilities and telecommunications. As some Asian currencies and equities swooned in mid 1997, many portfolio managers cut their allocation to the Asian debt market. Unfortunately, because of yield-maximization needs and a general reluctance to realize losses by some institutions (i.e., insurers), many investors reacted more slowly to credit-defensive positioning.

However, after a record number of "fallen angels" in 2002, which included such major credit bellwether issuers as WorldCom, and the misfortunes of many financial institutions in 2007–2008, investors became quicker to jettison potential problem credits from their portfolios. Ironically, once a credit is downgraded by the rating agencies, internal portfolio guidelines often dictate security liquidation immediately after the loss of single-A or investment-grade status. This is usually the worst possible time to sell a security and maximizes losses incurred by the portfolio.

New-Issue Swaps

New-issue swaps contribute to secondary turnover. Because of perceived superior liquidity, many portfolio managers prefer to rotate their portfolios gradually into more current and usually larger sized on-the-run issues. This disposition, reinforced by the usually superior market behavior of newer issues in the U.S. Treasury market (i.e., the on-the-run issues), has become a self-fulfilling prophecy for many credit issues. In addition, some managers use new-issue swaps to add exposure to a new issuer or a new structure.

Sector-Rotation Trades

Sector-rotation trades, within credit and among fixed income asset classes, have become more popular since the early 1990s. In this strategy, the manager shifts the portfolio from a sector or industry that is expected to underperform to a sector or industry that is believed will outperform on a total-return basis. With the general development of enhanced liquidity and lower trading transaction costs during non-crisis periods across the global bond market in the early twenty-first century, sector-rotation trades have become more prevalent in the credit asset class.

Such intra-asset class trading has played a major role in differentiating performance among credit portfolio managers. For example, as soon as the Fed launched its preemptive strike against inflation in February 1994, some investors correctly exchanged fixed-rate corporates for floating-rate corporates. In 1995, the specter of U.S. economic weakness prompted some investors in high-yield corporates to rotate from consumer-cyclical sectors such as autos and retailing into consumer noncyclical sectors such as food, beverage, and health care. Anticipating slower U.S. economic growth in 1998 induced a defensive tilt by some portfolio managers away from other cyclical groups such as paper and energy. The resurrection of Asian and European economic growth in 1999 stimulated increased portfolio interest in cyclicals, financial institutions, and energy debt. Credit portfolio managers could have avoided a great deal of portfolio performance disappointment in 2002 by underweighting utilities and many industrial sectors and again in 2007 by underweighting financial firms.

Curve-Adjustment Trades

Yield-curve-adjustment trades, or simply, *curve-adjustment trades,* are taken to reposition a portfolio's duration. For most credit investors, their portfolio duration is typically within a range from 20% below to 20% above the duration of the benchmark index. If credit investors could have predicted U.S., euro, and yen yield-curve movements perfectly in 2002 and in 2008, then they would have increased their credit portfolio duration at the beginning of 2002 and 2008 in anticipation of a decrease in interest rates. Although most fixed income investors prefer to alter the duration of their aggregate portfolios in the more-liquid Treasury market, strategic portfolio duration tilts also can be implemented in the credit market.

Such trades also are executed in anticipation of changes in the credit term structure or credit curve. For example, if a portfolio manager believes that credit-spreads will tighten (either overall or in a particular sector), with rates in general remaining relatively stable, then she might shift the portfolio's exposure to longer-spread-duration credit issues in her preferred sectors.

Structure Trades

Within the set of investment-grade, fixed-rate credit securities, *structure trades* have become rarer as the global credit markets have become more homogeneous (intermediate bullets). Structure trades are swaps into structures (e.g., callable structures, bullet structures, and putable structures) that are expected to have better performance given expected movements in volatility and the shape of the yield-curve. Structure trades also encompass swaps from less stringent issue indentures into tighter indentures that may afford bond investors greater protection should the issuer encounter financial difficulties. By expanding the choice set from fixed credit-only debt to include floating rate, preferred, preference, and even convertible securities, structural trades remain very common. The following examples illustrate the portfolio benefits of sound structure trades.

- The plunge in U.S. interest rates and escalation of yield-curve volatility during the second half of 1998 restrained the performance of callable structures compared with bullet structures.
- The upward rebound in U.S. interest rates and the fall in interest-rate volatility during 1999 contributed to the relative outperformance of callable structures versus bullet structures.
- A swap from floating-rate debt to fixed-rate debt would have aided credit portfolios at the beginning of global central bank easing cycles in 2001 and 2007.
- A rotation from conventional investment-grade credit debt into riskier subordinated structures, preferred stock, and convertibles in March 2009 would have markedly boosted portfolio performance.

Basis Trades

Traders and asset managers regularly prowl the global credit asset class for discrepancies, even slight, among bond, nominal spread, OAS, interest-rate swap spread, and credit default swap spread values for the same and similar issues. These discrepancies may give rise to advantageous *basis trade* swaps.

Cash-Flow Reinvestment

Cash-flow reinvestment forces investors into the secondary market on a near-weekly basis. In some years, the sum of all coupon, maturity, and partial redemptions (via tenders, sinking funds, and other issuer prepayments) equals approximately 100% of all new gross issuance across the dollar bond market. Before the allocation of any net new investment in the bond market, investors have sufficient cash-flow reinvestment to absorb nearly all new bond supply. Some portfolio cash inflows occur during interludes in the primary market, or the composition of recent primary supply may not be compatible with portfolio objectives. In these periods, credit portfolio managers must shop the secondary market for investment opportunities to remain fully invested or temporarily replicate the corporate index by using CDS and financial futures. Portfolio managers who incorporate analysis of cash-flow reinvestment into their valuation of the credit market can position their portfolios to take advantage of this cash-flow reinvestment effect on spreads.

Trading Constraints

Portfolio managers also should review their main rationales for not trading. Some of the best investment decisions are not to trade. Conversely, some of the worst investment decisions emanate from stale views based on dated and anachronistic constraints (e.g., avoid investing in bonds rated below Aa/AA). The best portfolio managers retain very open minds, constantly self-critiquing both their successful and unsuccessful methodologies.

Portfolio Constraints

Collectively, portfolio constraints are the single biggest contributor to the persistence of market inefficiency across the global credit market. Here are some examples:

- Because many asset managers are limited to holding securities with investment-grade ratings, they are forced to sell immediately the debt of issuers who are downgraded to speculative ratings (Ba1/BB+ and below). In turn, this selling at the time of downgrade provides an opportunity for investors with more flexible constraints to buy such newly

downgraded securities at a temporary discount (provided, of course, that the issuer's creditworthiness stabilizes after downgrade).

- Some Sovereign Wealth Funds and U.S. state employee pension funds cannot purchase credit securities with ratings below A3/A– owing to administrative and legislative guidelines.
- Some U.S. pension funds also have limitations on their ownership of MTNs and non-U.S. corporate issues.
- Regulators have limited U.S. insurance companies' investment in high-yield corporates.
- Some European investors are restricted to issues rated at least single-A and sometimes Aa3/AA– and above, created originally in annual-pay Eurobond form.
- Some investors are confined to their local currency market—yen, sterling, euro, U.S. dollar. Often the same issuer, such as GE Capital, will trade at different spreads in diverse local markets.
- Globally, many commercial banks must operate exclusively in the floating-rate realm; all fixed-rate securities, unless converted into floating-rate cash-flows via an interest-rate swap, are prohibited.

"Story" Disagreement

"Story" disagreement can work to the advantage or disadvantage of a portfolio manager. Traders, salespersons, sell-side analysts and strategists, and buy-side credit researchers have dozens of potential trade rationales that supposedly will enhance portfolio performance. The proponents of a secondary trade may make a persuasive argument, but the portfolio manager may be unwilling to accept the "shortfall risk" if the investment recommendation does not provide its expected return. For example, in early 1998, analysts and investors alike were divided equally on short-term prospects for better valuations of Asian sovereign debt. After a very disappointing 1997 for Asian debt performance, Asia enthusiasts had little chance to persuade pessimists to buy Asian debt at the beginning of 1998. Technically, such lack of consensus in the credit market signals an investment with great outperformance potential. Indeed, most Asian debt issues recorded exceptional outperformance over the full course of 1998 and 1999. After a difficult 2002, the same "rebound effect" was observed in electric utilities during 2003. Of course, "story" disagreement also can work in the other direction. For example, Enron and Lehman Brothers were long viewed as very solid credits before their sudden bankruptcies in late 2001 and September 2008, respectively. An asset manager wedded to this long-term view might have been reluctant to act on the emergence of less favorable information about Enron in the summer of 2001 and about Lehman during early 2008.

Buy-and-Hold

Although many long-term asset/liability managers claim to have become more total-return-focused in the 1990s, accounting constraints (cannot sell positions at a loss compared with book cost or take too extravagant a gain compared with book cost) often limit the ability of these investors to trade. Effectively, these investors (mainly insurers) remain traditional-buy-and-hold investors. Some active bond managers have converged to quasi-buy-and-hold investment programs at the behest of consultants to curb portfolio turnover. In the aftermath of the "Asian Contagion" in 1997–1998 and the Great Recession–induced financial panic of September 2008–March 2009, this disposition toward lower trading turnover was reinforced by the temporary reduction in market liquidity provided by more wary bond dealers. As shown in 2000–2002 and over 2007–2010, however, a buy-and-hold strategy can gravely damage the performance of a credit portfolio. At the first signs of a system-wide credit event (systemic risk) or credit trouble for an issuer (idiosyncratic risk), many credit portfolios would have improved returns by reducing their exposure to the overall credit asset class or to a deteriorating credit. And in the case of systemic-risk events, subsequent relative portfolio performance would have been greatly aided by adding solid issues temporarily caught up in the credit market's transitory general dislocation.

Seasonality

Lower-quality credits (Baa/BBB's) tend to be more susceptible to underperformance during August–October as dealers and investors become more defensive with the approach of year-end. Conversely, lower-quality credits frequently outperform during the first quarter on optimistic hopes for strong economic, industry, issuer fundamentals for the full calendar year. Secondary trading slows at month end, more so at quarter end, and the most at the conclusion of calendar years. Dealers often prefer to reduce their balance sheets at fiscal year-end (December 31 or March 31 [Japan]). Also, portfolio managers take time to mark their portfolios, prepare reports for their clients, and chart strategy for the next investment period. During these intervals, even the most compelling secondary offerings can languish.

SPREAD ANALYSIS

By custom, some segments of the high-yield and emerging (EMG) debt markets still prefer to measure value by bond price or bond yield rather than spread. But for the rest of the global credit market, nominal spread (the yield difference between corporate and government bonds of similar maturities) has been the basic unit of both price and relative-value analysis for more than two centuries.

Alternative Spread Measures

Many U.S. practitioners prefer to value investment-grade credit securities in terms of option-adjusted spreads (OAS) so that they can be compared more easily to the volatility ("vol") sectors (mortgage-backed securities and U.S. agencies).[2] But given the rapid reduction of credit structures with embedded options since 1990 (see structural discussion above), the use of OAS in primary and secondary pricing has diminished within the investment-grade credit asset class. Moreover, the standard one-factor binomial models[3] do not account for credit-spread volatility. And given the exclusion of default risk in OAS option-valuation models, OAS valuation has seen only limited extension into the higher-risk markets of the quasi-equity, high-yield corporate, and EMG-debt asset classes.

Starting in Europe during the early 1990s and gaining momentum during the late 1990s, interest-rate swap spreads emerged as the common denominator to measure relative value across fixed- and floating-rate note credit structures. The U.S. investment-grade and high-yield markets eventually may rely more heavily on such swap spreads to be consistent with Europe and Asia. But with the exponential growth of the credit-default swap (CDS) market since approximately 2000, CDS spreads have emerged as the standard gauge of relative pricing for large credit issuers.

Other U.S. credit-spread calculations have been proposed from time-to-time, most notably using the U.S. agency benchmark curve. This short-lived suggestion in 2000 sprang from the fallacious assumption of a persistent U.S. budgetary surplus and significant liquidation of outstanding U.S. Treasury securities during the first decade of the twenty-first century. As again demonstrated by 2002, history teaches that long-term fiscal assumptions unfortunately often prove to be faulty. Although some practitioners may choose to derive credit-agency spreads for analytical purposes, this practice had little chance of becoming standard market convention.

Credit-default swap spreads have emerged as the latest valuation tool during the great stresses in the credit markets of 2000–2002 and 2007–2010. Most likely, credit-default swap (CDS) spreads will be used as a companion valuation reference to nominal spreads, OAS, and interest rate-swap spreads. The market, therefore, has an ability to price any credit instrument using multiple spread references. Historically, the basic spread measures used the Treasury yield-curve or Treasury spot-rate curve as the underlying benchmark. Given the potential that

2. These sectors are referred to as "vol" sectors because the value of the securities depends on expected interest rate volatility. These "vol" securities have embedded call options and the value of the options, and hence the value of the securities, depends on expected interest rate volatility.

3. The model is referred to as a "one-factor model" because only the short-term rate is the factor used to construct the tree.

swap spreads will become the new benchmark, these same measures can be performed relative to swaps rather than relative to U.S. Treasuries.

Here is an illustration of how a bond manager can use the interest-rate swap-spread framework. Suppose that a hypothetical Ford Motor 4½s of 2016 traded at a bid price (i.e., the price at which a dealer is willing to buy the issue) of 113 basis point over the five-year U.S. Treasury yield of 2.75%. This equates to a yield-to-maturity of 3.88% (2.75% + 113 basis points). On that date, five-year swap spreads were 83 basis points (to the five-year U.S. Treasury). Recall that swaps are quoted where the fixed-rate payer pays the yield on a Treasury with a maturity equal to the initial term of the swap plus the swap spread. The fixed-rate payer receives LIBOR flat; that is, no increment over LIBOR. Thus, if the bond manager invests in the Ford Motor issue and simultaneously enters into this five-year swap, the following would result:

Receive from Ford Motor (2.75% + 113 basis points)	3.88%
– Pay on swap (2.75% + 83 basis point)	3.58%
+ Receive from swap	LIBOR
Net	LIBOR + 30 basis points

Thus, a bond manager could exchange this Ford Motor bond's fixed coupon flow for LIBOR + 30 basis points. A total-return manager would want to take advantage of this swap by paying fixed and receiving floating if he expects interest rates to increase in the future.

The swaps framework allows managers (as well as issuers) to more easily compare securities across fixed-rate and floating-rate markets. The extension of the swap-spread framework may be less relevant for speculative-grade securities, in which default risk becomes more important. In contrast to professional money managers, individual investors are not comfortable using bond valuation couched in terms of swap spreads. The traditional nominal spread framework is well understood by individual investors, has the advantages of long-term market convention, and works well across the entire credit-quality spectrum from Aaas to Bs. However, this nominal spread framework does not work very well for investors and issuers when comparing the relative attractiveness between the fixed-rate and floating-rate markets.

Spread Tools

Investors also should understand how best to evaluate spread levels in their decision making. Spread valuation includes mean-reversion analysis, quality-spread analysis, and percent yield spread analysis.

Mean-Reversion Analysis

The most common technique for analyzing spreads among individual securities and across industry sectors is *mean-reversion analysis*. The *mean* is the average

value of some variable over a defined interval (usually one economic cycle for the credit market). The term *mean reversion* refers to the tendency for some variable's value to revert (i.e., move toward) its average value. Mean-reversion analysis is a form of relative-value analysis based on the assumption that the spread between two sectors or two issuers will revert back to its historical average. This would lead investors to buy a sector or issuer identified as "cheap" because historically the spread has been tighter and will eventually revert back to that tighter spread. Also, this would lead investors to sell a sector or issuer identified as "rich" because the spread has been wider and is expected to widen in the future.

Mean-reversion analysis involves the use of statistical analysis to assess whether the current deviation from the mean spread is significant. For example, suppose that the mean spread for an issuer is 80 basis points over the past six months and the standard deviation is 12 basis points. Suppose that the current spread of the issuer is 98 basis points. The spread is 18 basis points over the mean spread or, equivalently, 1.5 standard deviations above the mean spread. The manager can use that information to determine whether or not the spread deviation is sufficient to purchase the issue. The same type of analysis can be used to rank a group of issuers in a sector.

Mean-reversion analysis can be instructive as well as misleading. The mean is highly dependent on the interval selected. There is no market consensus on the appropriate interval, and "persistence" frequents the credit market, meaning that cheap securities, mainly a function of credit uncertainty, often tend to become cheaper. Rich securities, usually high-quality issues, tend to remain rich.

Quality-Spread Analysis

Quality-spread analysis examines the spread differentials between low- and high-quality credits. For example, portfolio managers would be well advised to consider the "credit upgrade trade" when quality spreads collapse to cyclical troughs. The incremental yield advantage of lower-quality products may not compensate investors for lower-quality spread expansion under deteriorating economic conditions. Alternatively, credit portfolio managers have long profited from overweighting lower-quality debt at the outset of an upward turn in the economic cycle.

Percent Yield-Spread Analysis

Dating from the early twentieth century, *percent yield-spread analysis* (the ratio of credit yields to government yields for similar-duration securities) is another popular technical tool used by some investors. This methodology has serious drawbacks that undermine its usefulness. Percent yield spread is more a derivative than an explanatory or predictive variable. The usual expansion of credit percent yield spreads during low-rate periods such as 1997, 1998, 2002, and 2008–2010 overstates the risk as well as the comparative attractiveness of credit debt. And the typical contraction of credit percent yield-spreads during upward

shifts of the benchmark yield-curve does not necessarily signal an imminent bout of underperformance for the credit asset class. Effectively, the absolute level of the underlying benchmark yield is merely a single factor among many factors (demand, supply, profitability, defaults, etc.) that determine the relative value of the credit asset class. These other factors can offset or reinforce any insights derived from percent yield-spread analysis.

STRUCTURAL ANALYSIS

As explained earlier in this chapter, there are bullet, callable, putable, and sinking fund structures. *Structural analysis* is simply analyzing the performance of the different structures discussed throughout this chapter. While evaluating bond structures was extremely important in the 1980s, it has become less influential in the credit bond market since the mid 1990s for several reasons. First, the European credit bond market almost exclusively features intermediate bullets. Second, as can be seen in Exhibit 51–6, the U.S. credit and the global bond markets have moved to embrace this structurally homogeneous European bullet standard. Plenty of structural diversity still resides within the U.S. high-yield and EMG debt markets, but portfolio decisions in these speculative-grade sectors understandably hinge more on pure credit differentiation than the structural diversity of the issue-choice set.

Still, structural analysis can enhance risk-adjusted returns of credit portfolios. Leaving credit aside, issue-structure analysis and structural allocation decisions usually hinge on yield-curve and volatility forecasts, as well as interpretation of option-valuation model outputs (see the discussion below). This is also a key input in making relative-value decisions among structured credit issues, mortgage-backed securities, and asset-backed securities. In the short run and assuming no change in the perceived creditworthiness of the issuer, yield-curve and volatility movements largely will influence structural performance. Investors also should take into account long-run market dynamics that affect the composition of the market and, in turn, credit index benchmarks.

EXHIBIT 51–6

Changing Composition of the U.S. Investment-Grade Credit Markets*

	1990 (%)	2003 (%)
Bullets	24	94
Callables	72	3
Sinking funds	32	1
Putables	5	2
Zeros	4	N/A

*Figures in table do not add to 100% given that some structures may have contained multiple options (e.g., a callable corporate bond also may have a sinking fund and put provision).
Source: Lehman Brothers U.S. Investment-Grade Credit Index.

Specifically, callable structures have become rarer in the U.S. investment-grade credit bond market with the exception of the 2000 inversion. This is due to an almost continuously positively sloped U.S. term structure since 1990 and the yield-curve's intermittent declines to approximately multi-decade lows in 1993, 1997, 1998, 2002, and 2008–2010. As a result, the composition of the public U.S. corporate bond market converged toward the intermediate-bullet Eurobond and euro-denominated bond market. To see this, we need only look at the structure composition of Lehman's U.S. Investment-Grade Credit Bond Index. Bullets increased from 24% of this index at the start of 1990 to 96.0% (principal-value basis) by the end of 2010. Over this interval, callables declined at a remarkable rate from 72% to just a 3.5% index share. Sinking-fund structures, once the structural mainstay of natural-gas pipelines and many industrial sectors, are on the "structural endangered species list" with a drop from 32% of the public bond market in 1990 to only 0.1% in 2010. Despite several brief flurries of origination in the mid 1990s and the late 1990s introduction of callable/putable structures, putable structure market share fell from 5% in 1990 to 0.4% by 2010. Pure corporate zeros are in danger of extinction with a fall from 4% market share in 1990 to negligible by 2010.

Bullets

Here is a review of how different types of investors are using bullet structures with different maturities.

Front-end bullets (i.e., bullet structures with one- to five-year maturities) have great appeal for investors who pursue a "barbell strategy." There are "barbellers" who use credit securities at the front or short end of the curve and Treasuries at the long end of the yield-curve. There are non-U.S. institutions who convert short bullets into floating-rate products by using interest-rate swaps. The transactions are referred to as "asset swaps," and the investors who employ this transaction are referred to as "asset swappers."

Intermediate credit bullets (5- to 12-year maturities), especially the 10-year maturity sector, have become the most popular segment of the U.S. and European investment-grade and high-yield credit markets. Fifteen-year maturities, benchmarked off the 10-year bellwether Treasury, are comparatively rare and have been favored by banks that occasionally use them for certain types of swaps. Because new 15-year structures take five years to descend along a positively sloped yield-curve to their underlying 10-year bellwether, 15-year maturities hold less appeal for many investors in search of return through price appreciation emanating from benchmark rolldown. In contrast, rare 20-year structures have been favored by many investors. Spreads for these structures are benched off the 30-year Treasury. With a positively sloped yield-curve, the 20-year structure provides higher yield than a 10- or 15-year security and less vulnerability (lower duration) than a 30-year security.

The 30-year maturity is the most popular form of long-dated security in the global credit market. In 1992, 1993, late 1995, 1997, and 2010, there was

a minor rush to issue 50-year (half-centuries) and 100-year (centuries) securities in the U.S. credit bond market. These longer-dated securities provide investors with extra positive convexity for only a modest increase in effective (or modified-adjusted) duration. In the wake of the "Asian contagion" and especially the "great spread-sector crash" of August 1998 as well as the Great Recession of 2007–2009, the cyclic increases in risk aversion and liquidity premiums greatly reduced both issuer and investor interest in these ultralong maturities.

Callables

Typically after a 5- or 10-year wait (longer for some rare issues), credit structures are callable at the option of the issuer at any time. Call prices usually are set at a premium above par (par + the initial coupon) and decline linearly on an annual basis to par by 5 to 10 years prior to final scheduled maturity. The ability to refinance debt in a potentially lower-interest-rate environment is extremely valuable to issuers. Conversely, the risk of earlier-than-expected retirement of an above-current market coupon is bothersome to investors.

In issuing callables, issuers pay investors an annual spread premium (about 20–40 basis points for high-quality issuers) for being long (from an issuer's perspective) the call option. Like all security valuations, this call premium varies through time with capital market conditions. Given the higher chance of exercise, this call option becomes much more expensive during low-rate and high-volatility periods. Since 1990, this call premium has ranged from approximately 15 to 50 basis points for investment-grade issuers. Callables significantly underperform bullets when interest rates decline because of their negative convexity. When the bond market rallies, callable structures do not fully participate given the upper boundary imposed by call prices. Conversely, callable structures outperform bullets in bear bond markets as the probability of early call diminishes.

Sinking Funds

A sinking-fund structure allows an issuer to execute a series of partial calls (annually or semiannually) prior to maturity. Issuers also usually have an option to retire an additional portion of the issue on the sinking-fund date, typically ranging from one to two times the mandatory sinking-fund obligation. Historically, especially during the early 1980s, total-return investors favored the collection of sinking-fund structures at subpar prices. These discounted sinking funds retained price upside during interest-rate rallies (provided the indicated bond price remained below par), and given the issuers' requirement to retire at least annually some portion of the issue at par, the price of these sinking-fund structures did not fall as much compared with callables and bullets when interest rates rose. It should be noted that astute issuers with strong liability management

skills sometimes can satisfy such annual sinking-fund obligations in whole or in part through prior open-market purchases at prices below par. Nonetheless, this annual sinking-fund purchase obligation by issuers limits bond price depreciation during periods of rising rates.

Putables

Conventional put structures are simpler than callables. Yet, in trading circles, put bond valuations often are the subject of debate. American-option callables grant issuers the right to call an issue at any time at the designated call price after expiration of the noncallable or nonredemption period. Put bonds typically provide investors with a onetime, one-date put option (European option) to demand full repayment at par. Less frequently, put bonds include a second or third put option date. A very limited number of put issues afford investors the privilege to put such structures back to the issuers at par in the case of rating downgrades (typically to below investment-grade status).

Thanks to falling interest rates, issuers shied away from new put structures as the 1990s progressed. Rather than incur the risk of refunding the put bond in 5 or 10 years at a higher cost, many issuers would prefer to pay an extra 10 to 20 basis points in order to issue a longer-term liability.

Put structures provide investors with a partial defense against sharp increases in interest rates. Assuming that the issuer still has the capability to meet its sudden obligation, put structures triggered by a credit event enable investors to escape from a deteriorating credit. Perhaps because of its comparative scarcity, the performance and valuation of put structures have been a challenge for many portfolio managers. Unlike callable structures, put prices have not conformed to expectations formed in a general volatility–valuation framework. Specifically, the implied yield volatility of an option can be computed from the option's price and a valuation model. In the case of a putable bond, the implied volatility can be obtained using a valuation model such as the binomial model. The implied volatility should be the same for both puts and calls, all factors constant. Yet, for putable structures, implied volatility has ranged 4% to 9% since 1990, well below the 10% to 20% volatility range associated with callable structures for the same time period. This divergence in implied volatility between callables (high) and putables (low) suggests that asset managers, often driven by a desire to boost portfolio yield, underpay issuers for the right to put a debt security back to the issuer under specified circumstances. In other words, the typical put bond should trade at a lower yield in the market than is commonly the case.

Unless put origination increases sharply, allowing for greater liquidity and the creation of more standardized trading conventions for this rarer structural issue, this asymmetry in implied volatility between putable and corporate structures will persist. Meanwhile, this structure should be favored as an

outperformance vehicle only by investors with a decidedly bearish outlook for interest rates.

CREDIT-CURVE ANALYSIS

The rapid growth of credit derivatives since the mid 1990s has inspired a groundswell of academic and practitioner interest in the development of more rigorous techniques to analyze the term structure (1–100 years) and credit structure (Aaa/AAA through B2/Bs) of credit-spread curves (higher-risk, higher-yield securities trade on a price rather than a spread basis).

Credit curves, both term structure and credit structure, are almost always positively sloped. In an effort to moderate portfolio risk, many portfolio managers take credit risk in short and intermediate maturities and substitute less-risky government securities in long-duration portfolio buckets. This strategy is called a *credit barbell strategy*. Accordingly, the application of this strategy diminishes demand for longer-dated credit risk debt instruments by many total-return, mutual fund, and bank portfolio bond managers. Fortunately for credit issuers who desire to issue long maturities, insurers, and pension plan sponsors often meet long-term liability needs through the purchase of credit debt with maturities that range beyond 20 years.

Default risk increases nonlinearly as creditworthiness declines. The absolute risk of issuer default in any one year remains quite low through the investment-grade rating categories (Aaa/AAA to Baa3/BBB–). But investors constrained to high-quality investments often treat downgrades like quasi-defaults. In some cases, such as a downgrade from single-A to the Baa/BBB category, investors may be forced to sell securities under rigid portfolio guidelines. In turn, investors justifiably demand a spread premium for the increased likelihood of potential credit difficulty as rating quality descends through the investment-grade categories.

Credit-spreads increase sharply in the high-yield rating categories (Ba1/BB+ through D). Default, especially for weak single-Bs and CCCs, becomes a major possibility. The credit market naturally assigns higher and higher risk premia (spreads) as credit and rating risk escalate. Exhibit 51–7 shows the credit curve for two credit sectors (Baa and single-A industrials) and also illustrates that a higher spread is required as maturity lengthens.

In particular, the investment-grade credit market has a fascination with the slope of issuer credit curves between 10- and 30-year maturities. Like the underlying Treasury benchmark curve, credit-spread curves change shape over the course of economic cycles. Typically, spread curves steepen when the bond market becomes more wary of interest-rate and general credit risk. Spread curves also have displayed a minor propensity to steepen when the underlying benchmark curve flattens or inverts. This loose spread-curve/yield-curve linkage reflects the diminished appetite for investors to assume both curve and credit risk at the long end of the yield-curve when higher total yields may be available in shor and intermediate-credit products.

EXHIBIT 51–7

CREDIT ANALYSIS

In the continuous quest to seek credit upgrades and contraction in issuer/issue spread resulting from possible upgrades and, more important, to avoid credit downgrades resulting in an increase in issuer/issue spread, superior credit analysis has been and will remain the most important determinant of credit bond portfolio relative performance. Credit screening tools tied to equity valuations, relative spread movements, and the Internet (information available tracking all related news on portfolio holdings) can provide helpful supplements to classic credit research and rating agency opinions. But self-characterized credit models, relying exclusively on variables such as interest-rate volatility and binomial processes imported from option-valuation techniques, are not especially helpful in ranking the expected credit performance of individual credits such as IBM, British Gas, Texas Utilities, Pohang Iron & Steel, Sumitomo, and Brazil.

Credit analysis is both nonglamorous and arduous for many top-down portfolio managers and strategists, who focus primarily on macro variables. Genuine credit analysis encompasses actually studying issuers' financial statements and accounting techniques, interviewing issuers' managements, evaluating industry issues, reading indentures and charters, and developing an awareness of (not necessarily concurrence with) the views of the rating agencies about various industries and issuers.

Unfortunately, the advantages of such analytical rigor may clash with the rapid expansion of the universe of issuers of credit bonds. There are approximately 5,000 different credit issuers scattered across the global bond market. With continued privatization of state enterprises, new entrants to the high-yield market, and expected long-term growth of the emerging-debt markets, the global roster of issuers could swell to 7,500 by 2025. The sorting of this expanding roster of global credit issues into outperformers, market performers, and underperformers demands establishing and maintaining a formidable credit-valuation function by asset managers.

ASSET ALLOCATION/SECTOR ROTATION

Sector rotation strategies have long played a key role in equity portfolio management. In the credit bond market, "macro" sector rotations among industrials, utilities, financial institutions, sovereigns, and supranationals also have a long history. During the last quarter of the twentieth century, there were major variations in investor sentiment toward these major credit sectors. Utilities endured market wariness about heavy supply and nuclear exposure in the early to mid 1980s. U.S. and European financial institutions coped with investor concern about asset quality in the late 1980s and early 1990s. Similar investor skittishness affected demand for Asian financial institution debt in the late 1990s. Industrials embodied severe "event risk" in the middle to late 1980s, recession vulnerability during 1990–1992, a return of event risk in the late 1990s amid a general boom in corporate mergers and acquisitions, and a devastating series of accounting and corporate governance blows during 2001–2002. Sovereigns were exposed to periodic market reservations about the implications of independence for Quebec, political risk for various countries (i.e., Russia), the effects of the "Asian contagion" during 1997–1998, and outright defaults such as Argentina (2001).

In contrast, "micro" sector rotation strategies have a briefer history in the credit market. A detailed risk/return breakdown (i.e., average return and standard deviation) of the main credit subsectors (i.e., banks, brokerage, energy, electrics, media, railroads, sovereigns, supranationals, and technology) was not available from credit index providers until 1993 in the United States and until 1999 in Europe. Beginning in the mid 1990s, these "micro" sector rotation strategies in the credit asset class have become much more influential as portfolio managers gain a greater understanding of the relationships among intracredit sectors from these statistics.

Exhibit 51–8 illustrates the main factors bearing on sector rotation and issuer selection strategies. For example, an actual or perceived change in rating agency philosophy toward a sector and a revision in profitability expectations for a particular industry represent just two of many factors that can influence relative sectoral performance.

Common tactics to hopefully enhance credit portfolio performance are also highlighted in Exhibit 51–8. In particular, seasonality again deserves comment.

EXHIBIT 51–8

Some Outperformance Methodologies

The annual rotation toward risk aversion in the bond market during the second half of most years contributes to a "fourth-quarter effect;" that is, there is underperformance of lower-rated credits, Bs in high-yield and Baas in investment-grade, compared with higher-rated credits. A fresh spurt of market optimism greets nearly every new year. Lower-rated credit outperforms higher-quality credit. This is referred to as the "first-quarter effect." This pattern suggests a very simple and popular portfolio strategy: underweight low-quality credits and possibly even credit products altogether until the mid-third quarter of each year and then move to overweight lower-quality credits and all credit products in the fourth quarter of each year.

KEY POINTS

- As prescribed in capital market theory, investors should be rewarded for the assumption of incremental risk. Reality conforms to theory in the global credit market. Over the long run, credit products provide higher long-term returns than presumably risk-free government securities.
- Credit returns and risk are viewed as "asymmetric." On occasion, asset managers may suffer large, transitory relative underperformance to Treasuries with the onset of systemic risk event (i.e., the Financial Panic

in September 2008). And the price of individual credit securities may tumble from the par vicinity to zero in the event of default.

- Credit bond portfolio management requires more work and asset management firm infrastructure than other debt asset classes. There are thousands of credit choices, dozens of security forms, and multiple structures, and the size of the global credit asset class will accelerate during the twenty-first century thanks to the entrance of new emerging market based issuers.
- Global bond management philosophy has evolved rapidly over the past two decades. The arrival of the euro in 1999 curbed the use of currency strategies. Major portfolio-duration bets (more than 10% above or below the duration of an index benchmark) have become less common by asset managers because of frequent duration-timing disappointments. The use of CDS has expanded. New quantitative tools to assist in relative value rankings and asset allocation (i.e., risk budgeting) have proliferated. And particularly at large asset management firms, credit portfolios have truly become globalized.
- In conjunction with the demonstrably higher long-term returns of corporates and an ongoing migration from "government-only index benchmarks" to "government plus corporate and securitized index benchmarks," this reduction in currency and curve timing has propelled investor interest in global credit portfolio optimization as a path to more consistent overall portfolio outperformance in an increasingly competitive asset management industry.

CHAPTER
FIFTY-TWO

ELEMENTS OF MANAGING A HIGH-YIELD BOND PORTFOLIO

MARK R. SHENKMAN
President, Chief Investment Officer
Shenkman Capital Management, Inc.

NICHOLAS R. SARCHESE, CFA
Senior Vice President
Shenkman Capital Management, Inc.

High-yield portfolio management involves the art and science of matching a portfolio's investments to its underlying objectives and overall risk profile. The focus is to balance risk against performance with the goal of achieving superior risk-adjusted returns over an entire credit cycle. From a portfolio management perspective, the high-yield market is a unique asset class due to the fact that high-yield securities exhibit the characteristics of both debt instruments and equities. Given the greater risk associated with highly levered companies, changes in the underlying fundamental credit profile are the primary driver of return over time as default loss is a key concern. However, as part of the fixed income asset class, debt attributes of the security, such as coupon, maturity, covenants, and ratings, also affect prices and performance.

High-yield bonds offer significant incremental return and income as compared with most other fixed income investments. However, it is essential to keep in mind their asymmetrical risk profile. That is, a bond's upside is generally limited to its face value at maturity or early redemption premium, while the downside could include an entire loss of principal in a default. In order to capture the attractive incremental returns and spreads offered by investing in high-yield bonds, minimizing default and credit loss are crucial components to achieving this goal.

Properly assessing and managing risk are critical elements of managing a high-yield portfolio. Risk controls require developing insightful and comprehensive procedures to identify and control risk across the following three key areas:

1. Bottom-up credit/security analysis
2. Top-down high-yield market drivers and macro considerations
3. Portfolio considerations

EXHIBIT 52–1

Elements of Managing a High-Yield Bond Portfolio

Exhibit 52–1 identifies these three areas and highlights the elements to consider. The most successful portfolio managers have the ability to assimilate all three areas as the intersection point is the nexus of the portfolio decision-making process. Each of these areas and their elements are discussed in further detail below.

Over the long term (and through various economic cycles), portfolio managers who have avoided defaults and major trading losses have typically outperformed various high-yield benchmarks.

BOTTOM-UP–CREDIT/SECURITY ANALYSIS[1]

While credit analysis is arguably the most important component of a bottom-up investment process, security structure/terms, covenants, trading liquidity factors and relative value ultimately determine if a "good credit" will make a

[1]This section is adapted from Nicholas Sarchese, Amy Levine, "Credit Analysis and Analyzing a High-Yield Issuance," Chapter 7 in William F. Maxwell, Mark R. Shenkman (ed.), *Leveraged Financial Markets: A Comprehensive Guide to High-Yield Bonds, Loans, and Other Instruments* (New York: McGraw-Hill, Inc., 2010).

EXHIBIT 52–2

Six Steps in Bottom-Up—Credit/Security Analysis

"good investment." Poor relative value and overpaying for a good credit could lead to underperformance. Weak trading liquidity factors can magnify the downside and disrupt the value equation in a negative surprise scenario. In executing a buy-sell decision, a step-by-step process is required to ensure consistency and disciplined decision making. Exhibit 52–2 highlights the six steps in analyzing a high-yield issuance. A checklist of positive and negative attributes should be utilized at each step. It is also important to emphasize that all of the bottom-up steps are significant in their own right. A favorable assessment on many of the steps may not necessarily outweigh an individual risk component that is identified in the process.

Step One: Credit Analysis

Thorough credit analysis is ultimately the foundation for a successful high-yield investment since its primary focus is to avoid defaults. A greater investment risk is getting the credit analysis wrong as opposed to potentially overpaying for a good credit. It is important to keep in perspective that the high-yield asset class involves highly levered companies that have disproportionately less margin for error. The asymmetrical upside/downside return profile of bonds also highlights

the importance of avoiding meaningful downside credit risk. In practice, the underperformance related to overpaying for a good credit pales in comparison to the ultimate downside in holding the bonds of a credit that defaults. Remember that a bond's upside is limited to par (plus perhaps an early takeout premium), while the downside is theoretically zero. If a bond drops from par to 50, it would take 10 bonds to advance five points each in order to recoup the 50-point decline in just one credit! Equity portfolios do not have this similar dynamic because one investment can soar by 500%, thereby offsetting the losses in numerous other transactions. However, the number of bonds in a portfolio that can jump five points or more may be limited.

Credit analysis can be simply defined as determining the borrower's ability to meet its interest and principal obligations when due. It is often identified with financial ratio analysis. However, true credit analysis is much more comprehensive and encompasses greater in-depth review. For example, two credits with identical financial ratios may not represent the same credit risk. As outlined in Exhibit 52–3, credit analysis can be divided into four key areas: business risk, financial risk, management/ownership risk, and covenant risk.

Thorough credit analysis is not complete without a detailed examination of all four risk factors. Weakness in any one of the four areas could offset the strength in the remaining three and result in high credit risk for a particular issuer (Exhibit 52–4).

Investors must focus their analysis on a "forward looking" view of all four risk areas. While historical results are important for perspective, ultimately it is the future credit trend that will dictate performance.

EXHIBIT 52–3

The Four Key Components of Credit Analysis

EXHIBIT 52–4

Credit Analysis Examples

Examples include:

Strong Financial Profile + Strong Management + Strong Covenant Protection

The strengths may not be able to offset a high business risk where the industry structure is unfavorable, and the company is weakly positioned

Strong Business/Industry Fundamentals + Strong Financial Profile + Reasonable Covenant Protection

The strengths may not be able to offset the negative impacts of a weak management team with aggressive financial policy – OR – Bondholder unfriendly private equity sponsor

Strong Business/Industry Fundamentals + Strong Financial Profile + Strong Management

The strengths may not be able to offset the negative impact of a weak covenant package

Strong Business/Industry Fundamentals + Strong Management + Strong Covenant Protection

The strengths may not be able to offset the financial risk of a company that is overlevered

Business Risk

Analyzing the business risk of a particular credit involves an assessment of both the industry risk and company-specific risk from more of a strategic perspective. This analysis should involve not only determining whether the industry structure and fundamentals are favorable, but ascertaining the company's strategic position within its industry. Even the best company in a given industry may not be able to withstand major structural changes.

Industry Analysis. High levels of debt can be manageable and appropriate for certain industries but not others. Some industries are more conducive to leverage because their high operating margins, solid growth rates, and consistency of earnings enable the companies within the sector to service a higher degree of indebtedness. Factors used to assess an industry include: stability of cash-flows, stage in industry lifecycle, capital intensity, cost structure/operating leverage, degree of rapid change, competitive forces, regulation, and pricing power. In addition to providing an enhanced credit profile, industries that possess more favorable outlooks also tend to trade better because of positive macro considerations and investor support.

Company Analysis. It is imperative to dissect a company's specific strengths and weaknesses and determine how it fits into its industry. For example, a company can operate in a growing industry but possess obsolete technology. Conversely,

a company can compete in a declining industry but have a leading market position and generate significant cash-flow. Factors to consider include:

- Size of the company
- Stage in company lifecycle
- Market position
- Diversification
- Potential for event risk

All of the above mentioned factors can impact the creditworthiness of the borrower.

Financial Risk

After assessing an industry and company's business risk, the next step is to consider the overall financial risk and credit profile of the borrower. This consideration should take into account the company's capitalization and degree of leverage. The fundamental operating outlook and credit profile of a company are critical variables that should drive bond performance. Moreover, a thorough analysis must evaluate the past financial results to understand the drivers of the business.

The key variables to financial risk include:

- The stability of cash-flows
- Recent and near term projected performance trends
- Stress testing (how well a company's credit profile can withstand negative surprise)
- Analysis of free cash-flow and the ability to de-lever
- Leverage and coverage statistics
- Cash and available liquidity
- Amortization/maturity schedule
- Quality and salability of assets
- Access to capital markets
- Asset coverage

Management/Ownership Risk

While factors relating to credit analysis are crucial, the senior management of the company are responsible for establishing goals, objectives, and strategic vision for the business. In the end, a great management team can make a significant difference in the performance of a security.

Direct Communications. Portfolio managers or research analysts should have direct contact with senior management (i.e., one-on-one meetings or calls, company visits, etc.). Direct access is the best way to understand and evaluate management and can provide greater insight into the risk parameters for a specific issuer. Moreover, analysts should maintain an ongoing dialogue with company managements. During times of duress, if management is inaccessible, investor confidence in the company could be shaken, and the bonds may underperform.

Quality of Management. The quality of the senior management team is significant in making a good investment. While successful companies must pursue effective strategies, development and execution of those strategies hinge on the management team in control. Although management assessment is somewhat subjective, and improves with experience, the best qualities to look for in a management team include: low turnover, tenure and reputation within the industry, strong track record, timeliness in filing financial statements, forthrightness in responding to questions, strategic vision, a deep bench, and successful completion of stated goals. Great business leaders are able to effectively communicate the company's strategy and vision, articulate the opportunities and risks confronting the company, and act decisively and proactively in times of change.

Private Equity Sponsors/Ownership. Often, a highly levered company may be owned by a private equity sponsor. In these cases, the equity sponsor drives the company's strategic direction and financial policies, while the operating senior management (i.e., CEO, COO, CFO) usually have less influence in the overall direction and financial risk tolerance of the company. It is always important to keep in mind that the interests of the private equity sponsor in many cases may not align with bondholders. For example, sponsors may declare a large cash dividend as quickly as possible to enhance their equity returns, although this action may lead to deterioration in the company's credit quality. If the sponsors have little capital at risk, they could try for a "swing for the fences" type strategy since they have little downside (having taken their invested capital out) but significant upside if the strategy pays off. This "no capital at risk" strategy is not ideal for bond investors, as the company may have little capital cushion, particularly in a faltering economy. The sponsor's investment track record, default history, and record in paying down debt should be carefully examined. Another factor is the percentage of equity owned by the management team. If equity ownership is spread throughout management, they are more likely to be deeply engaged in the success of the overall enterprise.

Financing Philosophy. Investors must consider both the ownership's and management team's intentions regarding the company's balance sheet. Is management comfortable operating with high levels of debt and leverage, or are they more conservative and prefer to have more financial flexibility and lower leverage? Is management comfortable with the current amount of debt or is debt pay down a

key priority? How committed is management to paying down debt? Is management opportunistic in that they would consider making an attractive acquisition even if it involved increasing the financial risk profile of the company? If the management team is comfortable with the current level of debt, they might focus on using cash-flow toward paying dividends, share buybacks, or funding additional acquisitions. If debt pay down is a key priority, and the company generates a large amount of free cash-flow, the issuer's credit metrics are likely to improve. Knowing management's philosophy towards debt is of vital importance in forecasting the company's credit profile as it will serve as a guide toward the application of free cash-flow. It also provides a guidepost from which to judge their success in achieving previously stated goals as well as their credibility. For example, if the management team has stated its intention to de-lever and then initiates a large stock buyback, the bonds are likely to underperform as the "credit story" has not met expectations, and investors may have diminished confidence in senior management.

Covenant Risk

A detailed examination of covenants is a critical part of credit analysis. Although each tranche of debt may contain its own specific debt covenants, collectively they impact the borrower's overall credit risk profile and financial flexibility. Evaluating the collective impact of all of the company's covenants (bank loan as well as bond covenants) is important in understanding the overall credit risk of a company. The presence of a strong covenant package within an issuer's bank loan may have significant influence on bond performance. In certain cases, limited covenant flexibility may improve the overall credit profile of the company because it could create the opportunity for early redemption at a premium or limit increases in financial risk. Conversely, there are cases where limited covenant flexibility may prove to be a significant risk to a borrower's credit profile as it could force a liquidity event at an inopportune time in the credit cycle. Covenants are covered in further detail as part of Step 3, the analysis of an individual security.

Step Two: Security Structure and Terms

A key consideration of a particular bond investment is its terms and structure. Most investors tend to favor bonds that possess terms and structure that are in line with or better than market standard. However, as terms evolve and change with market conditions, portfolio managers must understand the implications and risks associated with alternative structures, and if acceptable, ensure that they are compensated appropriately.

The following factors must be carefully evaluated.

- Issue size
- Ranking/seniority

- Maturity
- Coupon type
- Early redemption features

Issue Size

The issue size of a bond will influence its liquidity and general attractiveness to other constituents in the market. For example, an issue size that is less than $250 million may have a smaller investor base and therefore less trading liquidity. To the extent there is a seller of this security, the downside impact to the market may be greater given the lower trading liquidity and a narrower universe of investors willing to purchase a small, less liquid security. Conversely, mega-issues (greater than $1 billion issue size) may experience greater price volatility. As they tend to be liquid "benchmark" issues in the high-yield market, they may exhibit higher beta during aggressive movements in the overall market, as institutional investors are able to more easily execute trades and express their market sentiment.

Ranking/Seniority

The ranking and seniority of a bond are vital factors in assessing the risk and attractiveness of a security. Ranking and seniority refer to the location of the bond within the issuer's capital structure as well as the priority of claim in the event of bankruptcy. The ranking and seniority range from and include: senior secured, senior secured second-lien, senior unsecured, senior subordinated, subordinated, and structurally subordinated. The more senior securities in the capital structure are generally accompanied by lower relative yields. Additionally, investors must ascertain the level of guarantees provided and where the tranches of debt sit relative to the assets of the company as well as the ranking within the capital structure. Portfolio managers should properly identify the risk associated with the ranking/seniority terms of the specific security so that they can determine the appropriate yield.

Maturity

A bond's maturity involves both technical and credit considerations. From a top-down perspective, an investor may be concerned with a significant rise in interest rates and, therefore, favor a shorter maturity option within a given capital structure. From a bottom-up perspective, an investor may be comfortable with the short-term prospects and liquidity for a given credit, but much less comfortable with the longer-term viability of the company and, therefore, favor a shorter maturity option within a capital structure with multiple maturities. Lastly, uncommon maturity terms may lead to greater price volatility given the potentially smaller investor base interested in a "non-standard" bond. High-yield bonds have historically been structured with final maturities of between 7 and 10 years. More recently, however, issuers have come to market with longer maturities of 11 and 12 years to take advantage of the low interest-rate environment. These uncommon maturities have thus far been met with mixed results.

Coupon Type

While the high-yield market consists primarily of cash-pay bonds, alternative structures also exist, including: zero coupon, pay-in-kind (PIK), or PIK toggle. While the alternative structures tend to offer higher yields as a result of the less investor-friendly repayment terms, they also typically possess greater trading liquidity risk as they tend to appeal to a much smaller investor base within the high-yield universe.

Early Redemption Features

Early redemption features are common within the high-yield market. For example, the most typical bond structures are 8-year, noncall 4, or 10-year, noncall 5. This type of security is not callable for the first half of its life, but then is callable at the company's option and according to a schedule that pays a premium to face value which declines as it nears final maturity. More recently, issuers have come to market with less call protection in exchange for a small, additional premium. Portfolio managers must be careful in evaluating early redemption features that may have a significant impact on returns as they can limit a bond's potential upside.

Step Three: Covenants

Contained within the indenture of all high-yield bond offerings are certain covenants (or agreements) between the issuing company and bondholders. Covenants are essentially restrictions on the borrower/issuer imposed by the lender/bondholder that require the company to do or refrain from doing certain activities. The covenants are primarily designed to protect bondholders against credit deterioration that would hinder the company's ability to service the interest and repay the obligations on a timely basis.

Covenants are often referred to as "tight/strong" or "loose/weak," depending on the specific terms and ultimate financial flexibility they provide the issuer. A weak covenant package can significantly increase the risk of a high-yield bond investment, even though the credit's business and financial risk profiles can be strong. As a result, the covenant package may not protect the bondholders by prohibiting enough actions by the issuer that could be detrimental to its ability to repay the bonds and service the interest.

Covenant analysis is a crucial part of any high-yield bond investment process. While a strong covenant package cannot offset the risk of a weak credit, it may provide significant financial protection to the investor. A weak covenant package may not necessarily preclude investment in a particular issue; however, it may increase the yield an investor demands due to the higher level of risk.

From an investment standpoint, there are four key covenants to analyze, as follows: Limitation on Indebtedness, Restricted Payments, Change of Control, and Limitations on Asset Sales.

Limitation on Indebtedness

The limitation on indebtedness covenant restricts the amount of additional indebtedness that an issuer can incur. Unless it is kept in proportion to operating cash-flow and assets, additional indebtedness can ultimately dilute the claims of the existing bondholders and weaken the credit profile of the company due to the increased debt-service requirements.

Restricted Payments

The restricted payments covenant protects bondholders' interests in the assets of the company by restricting the company's ability to distribute money or assets outside the company, thereby preserving the company's ability to repay its indebtedness. Undesirable distributions and asset transfers that are limited by this covenant include dividends, repurchases of equity, investments in unrestricted third parties, and retiring debt that is subordinate to the bonds before retiring the bonds. It is important to recognize that the restricted payments covenant does not limit acquisitions and capital expenditures, both of which should result in incremental cash-flow and return on investment. The test is ultimately backward looking in that it determines whether the company has earned the right to make a payment to benefit the equity of the company as opposed to the debt.

Change of Control

The change of control covenant requires the issuer to offer to purchase the debt at 101% of principal if a change of control occurs. It is the bondholder's option to accept or decline the offer. In effect, this covenant gives a put option to the bondholder upon certain events. The rationale behind the change of control covenant is that it protects bondholders against a change in controlling interest by an owner who may have a different financial strategy for the issuer that could ultimately lead to deterioration in credit quality.

Limitation on Asset Sales

In contrast to its title, the asset sale covenant does not necessarily limit the ability of the issuer to sell assets. Its true purpose is to define the acceptable use of proceeds from asset sales. The proceeds must be used to permanently repay debt or to reinvest in replacement assets. The rationale is that the assets sold usually generate earnings and cash-flow to service debt and should be replaced with similar assets.

Step Four: Risk Assessment Checklist

One of the key methodologies to optimize a portfolio is to use a checklist of variables that can help to identify hidden risk factors. Similar to a pilot who is required to perform a checklist before any plane takes off, portfolio managers should engage in a similar rigid review. Exhibit 52–5 is a list of 25 factors that

EXHIBIT 52–5

Risk Assessment Checklist

	Yes	No	
1.			PIK/Toggle in Capital Structure
2.			Triple-C Rated on Both Sides
3.			Project Finance
4.			144A For Life
5.			Fallen Angel
6.			2nd or 3rd Tier Underwriter
7.			Deal Size <$250mm
8.			Weak Covenant Package
9.			Recession Prone Industry
10.			Leverage >6× or > 85% of Enterprise Value
11.			Long Duration (>10yrs)
12.			Highly Cyclical Industry
13.			Weak and/or Distrusted Management
14.			High Risk Default Industry or Previously Defaulted Company
15.			Sponsor Has Poor Track Record With Bondholders
16.			Current or Projected Negative Free Cash-Flow
17.			Little or No Hard Assets
18.			Dividend Deal
19.			Middle Market Company
20.			Debt at Holding Company & Structurally Subordinated to Other Debt
21.			Down Quarter and/or Down Year Projected
22.			Lead Underwriter is Also an Equity Holder in the Company
23.			Poor Information Flow or Management Contact
24.			Covenant Violation Forecast in Next 12–24 Months
25.			Significant Refinancing Required in Next 2 Years
			TOTAL

can cause unexpected losses and volatility. The more indicators that flash negative, the greater level of risk associated with the investment. This checklist is by no means a complete listing of *all* potential risk factors. However, it is meant to highlight certain risks that perhaps garner less focus and attention from investors.

Step Five: Trading/Liquidity Factors

While credit analysis is focused on assessing the financial risk of a particular bond issue, the analysis of trading and liquidity risk evaluates the additional volatility that may be experienced by a bond issue. Trading liquidity can hamper the performance of a bond issue that may possess a favorable credit risk profile, but the far more significant risk is that a poor trading liquidity profile could dramatically magnify the downside risk of a weak credit. It may be already difficult to garner investment interest and new buyers in a weak or deteriorating credit; however, it is considerably more challenging to develop new demand in a weak credit that also possesses poor trading liquidity. For example, a disappointing earnings announcement could result in a two-point drop in bond price if the issue possesses favorable trading liquidity, whereas the same announcement could result in a five-point (or greater) drop in price if the bond possesses thin trading liquidity. Portfolio managers should have extremely high conviction level in credits with limited liquidity and require higher returns in those situations.

Liquidity Risk[2]

Liquidity risk involves measuring the ability to sell a particular credit on a timely basis. While equities often trade on an organized stock exchange or electronically and buyers and sellers are matched, high-yield bonds trade over-the-counter. Bond investors are dependent on broker-dealers to make a market. Also, unlike equities, the majority of high-yield bonds do not trade on any given day. An interesting analogy is to think of the high-yield market as being like a lake that is one mile wide, but only inches deep. If a particular high-yield bond has limited liquidity, portfolio managers may be unable to execute their buy/sell decisions.

Portfolio managers should take into consideration the following key elements to assess the liquidity risk of a particular bond.

1. *Public or private company:* Private companies often possess less liquidity than public companies because there is either not enough information about the company in the market or the information is not widely dispersed. For example, a potential purchaser of an unregistered bond (e.g., Rule 144A) issued by a private company can usually get information about the issuer only by

[2]This section is adapted from Mark R. Shenkman, "Principles of Managing High-Yield Assets," Chapter 12 in *Leveraged Financial Markets: A Comprehensive Guide to High-Yield Bonds, Loans, and Other Instruments.*

requesting it from the underwriter or trading desk. New purchasers may be reticent to ask for the information because they may signal to the trading desk their intentions to purchase the bonds, thereby causing the broker-dealer to raise its offered price for the credit.

2. *Number of market makers and number of analysts following the issuer:* The fewer professionals on Wall Street who trade or actively "follow" a bond reduce the available information on a company. Bond issues that have only one market maker and no analyst coverage may be so illiquid that they "trade by appointment" (meaning that a seller has to give an order to a broker-dealer who then tries to sell the bond over a period of time).
3. *Number of tranches of debt in the capital structure:* The more tranches, or issues, of debt that a company has outstanding, the higher the probability that more traders and analysts will follow a given credit. A large number of tranches provides more activity in an issuer because there are paired-trade possibilities, such as shorting senior bonds and purchasing subordinated bonds. The ability to trade across the capital structure in one credit increases the universe of investors interested in the bonds.
4. *Accessibility of management:* Bonds issued by companies with inaccessible management typically inhibit trading activity because investors lack sufficient information to give them comfort or conviction, particularly in volatile markets. If a management team is unwilling to talk when times are good, they are even more unlikely to talk when times are bad!
5. *CDX-listed issuer:* The CDX is a widely traded index of 100 Credit Default Swaps (CDS) that mirrors the broader high-yield market. The CDX, the underlying CDS, and the underlying bonds are all linked by the arbitrage that exists if the CDX becomes too cheap compared with the CDS or the actual bonds. Therefore, underlying bonds of CDS in the CDX tend to trade more frequently because investors may be executing arbitrage trades. Moreover, the price of CDX-listed issues tends to be more volatile because they are the most liquid credits.
6. *Volume of trading activity according to TRACE:* Broker-dealers are required to report high-yield bond trades to a self-regulating organization that makes some trade details of certain high-yield bonds publicly available. This system is called TRACE (Trade Reporting and Compliance Engine). Bonds that have a TRACE history typically have more liquidity because historical patterns and data points can be obtained and measured.
7. *Issuer is a major company within its industry:* Bonds of companies that have a real "presence" in their respective industries tend to have more

liquidity for two reasons. First, if the underlying company is a major part of its industry, it becomes a proxy for the industry and allows investors to obtain exposure to a sector. Second, high-yield traders typically like to own and trade the largest credits in an industry sector.

8. *Size of issue:* The universe of potential buyers of a bond typically increases with the dollar size of the issue. The larger pool of potential purchasers increases the ability of a bondholder to sell a particular issue.
9. *Ratings of issuer and issue:* Higher-rated credits within the high-yield universe tend to trade more frequently because they are perceived as being more stable and have greater demand. Triple-C rated issues generally require more work and conviction to purchase, causing traders to be less willing to hold a bond that investors may need more time to analyze.
10. *Crossover credits:* Bonds that generate demand from both investment-grade and high-yield buyers, such as utilities, offer greater liquidity. High-yield bonds that are considered crossover companies typically generate a new class of investment-grade purchasers who from time-to-time dip down and buy the high-yield bond tranche. With a larger universe of such buyers and sellers, liquidity often improves.

Based on these 10 criteria, each credit should be designated as L1, L2, or L3. L1 credits are traded by multiple market-makers on a daily basis; L2 names are typically traded by two or more market-makers on a weekly basis; and L3 credits trade a few times per month by one or more market-makers, which can result in an inability to execute on a timely basis. In many cases, an L3 bond can become an "orphan" credit if the original underwriter no longer covers or makes a market in the credit.

The percentage of the portfolio represented by L1, L2, or L3 liquidity ratings should be calculated and monitored to determine the appropriate weighting in each category.

Step 6: Relative Value

Relative value is the final step in the bottom-up security analysis process. Once the credit and liquidity risks of an issue have been determined and evaluated, then the overall expected risk premium for the security can be appropriately established. Spread analysis is typically the most appropriate metric in determining if the security's return is commensurate with its overall credit and investment risk.

Risk/Reward

Determining relative value in the high-yield market is more an art than a science. The age-old maxim "Buyer Beware" rings loudly in high-yield as all risk is not created equal! For example, it is much easier to compare and value the

risk of financial leverage across two credits than it is to determine how much incremental return or yield is required to compensate for the potential risk presented by significant covenant flexibility that can be utilized to the detriment of bondholders. Some investors use ratings (usually assigned by Moody's and/or S&P) to determine their credit risk and then evaluate the spreads on that basis. For example, a single-B rated issue yielding 500 basis points over riskless U.S. Treasuries may be considered attractive relative to another single-B rated issue yielding 350 basis points, or versus the current high-yield single-B index average spread of 400 basis points. However, in order to make this assessment, investors must assume that the credit ratings themselves are accurate, and that they are a "leading" indicator of credit risk. More importantly, investors should realize that credit ratings do not contemplate many of the investment risks discussed above, such as bond covenants, size of issue, quality of underwriter(s), number of market makers, Wall Street sponsorship, and information flow, to list a few. Relying on the credit rating alone to determine risk will not give a complete picture and can be a perilous exercise during certain stages of the credit cycle.

Comparables

The basic formula for assessing relative value is to compare the spread of the security being evaluated to the bond spreads of industry peers and other credits of similar risk. Exhibit 52–6 is a typical "comp sheet" that can help assess the relative value of one bond versus another.

Analyzing the credit comparable on the next page, it becomes apparent that Company C is a weaker credit. As compared to the other two companies, Company C has higher leverage, weak interest coverage, negative cash-flow, and significant near-term amortization for which it does not appear to have ample liquidity to address. Given the higher risk credit profile, the spread on Company C's subordinated notes is meaningfully wider than its comparables as one would expect. In contrast, Company A's stronger credit profile has resulted in a meaningfully tighter spread than its comparables. Although it also has substantial debt amortization in the current year, it appears to have ample liquidity (as measured by its cash and availability) to absorb the amortization. Credit comparables should include a snapshot of the trailing 12-month operating results as well as a forward looking credit profile for the next 12 months.

Quadrant Analysis

Many investors use credit ratings to determine risk and evaluate comparable spreads. Given the prevalence of ratings in the marketplace and their acceptance among market participants, portfolio managers should not rely on these ratings as a primary assessment of creditworthiness. Rather, portfolio managers should construct a more comprehensive risk assessment that can be tailored to incorporate factors they deem appropriate.

Constructing a risk/return matrix can be helpful in determining a framework. Credits can be divided into four quadrants as shown in Exhibit 52–7 based on their level of risk and potential return. A description of each of these quadrants is as follows:

- *Quadrant I:* Solid credits with strong credit statistics, moderate leverage, and strong free cash-flow. Typical characteristics would include companies with predictable and improving cash-flows; deleveraging companies; and companies that have substantial assets well in excess of debt. Objective: Capital Preservation

EXHIBIT 52–7

Quadrant Matrix

- *Quadrant II:* Good credits with significant leverage that show stability and/or improvement in their credit profile via improved results and lower leverage. Quadrant II companies can appreciate or depreciate depending upon their ability to execute their business plans, and ultimate credit trend. These companies typically possess above average creditworthiness with adequate balance sheets and relatively weak asset value coverage of their total debt. Objective: Total Return
- *Quadrant III:* Weak credits with extremely high leverage and deteriorating or at risk credit trends. These credits have a small margin for error and, therefore, require higher yields to compensate bondholders for the additional risk. Typical characteristics include minimal to negative free cash-flow (best measured relative to total debt) and deteriorating credit statistics. They may also include relatively new companies, companies with large capital requirements, and companies with aggressive capital structures that utilize zero coupon, PIK or

PIK/toggle notes. Asset value coverage of total debt is typically weak. Objective: High Risk/High Return

- *Quadrant IV:* Troubled credits that are stressed or distressed and could be in actual or technical violation of covenants. Bonds are likely to be impaired and therefore should require much higher equity-like returns. Objective: Capital Appreciation

When assigning quadrants to specific credits, they should be evaluated with an emphasis on the prospective, forward-looking view because the markets are more focused on where a credit is going rather than where it has been. Portfolio managers who are better able to correctly forecast credit trends should outperform their peers. Placing too much emphasis on past results could ultimately provide a myopic risk assessment and thereby limit the risk/reward equation and relative value analysis.

Within the quadrant concept, spreads can be analyzed relative to credits within the same quadrant. Given the potentially wide spectrum of credit quality within a specific quadrant, issuers may be further subdivided into lower and upper quadrants for greater segmentation. Once quadrants have been assigned, portfolio managers should compare spreads of companies within the same quadrant that are most similar. When possible, comparisons should be to companies within the same industry and quadrant. Other relative considerations include trading history, stock and bank loan/CDS prices, and duration.

Scenario Analysis

Scenario analysis is another tool to better identify relative value and determine an appropriate investment recommendation. This analysis is particularly useful in circumstances with multiple outcomes or potential event risk.

In Exhibit 52–8, the subject company has just announced a significant acquisition, although financing has not yet been determined. After assessing the amount of flexibility provided by the company's existing covenants as well as taking into account current capital market conditions for debt and equity, the analyst can utilize a scenario analysis to determine a potential trading recommendation.

EXHIBIT 52–8

Scenario Analysis Example

	Probability	Bond Price	Yield-to-Worst	Spread-to-Worst	Leverage Ratio
Current Trading Level		98	8.3%	487bp	5.0x
Scenario A	75%	92	9.4%	596bp	6.3x
Scenario B	25%	99	8.2%	470bp	4.7x

Assumptions:
Scenario A: assumes 100% debt financed acquisition.
Scenario B: assumes acquisition is financed with 60% equity and 40% debt.

Given management's prior comments and long standing financial policy, the analyst has assigned a 75% probability to a debt-financed acquisition as opposed to a more balanced combination of debt and equity. Likely potential trading levels are then assigned to each of the scenarios above based on the pro forma risk profiles. This scenario analysis indicates that there is six points of potential downside on the higher probability outcome as opposed to one point of upside on the less likely outcome. Based on this analysis, the recommendation would likely be to sell or reduce the position if possible, or at least proceed with caution.

Trading History

To the extent an issuer has had bonds outstanding for a period of time, portfolio managers should examine the trading history of those bonds. Exhibit 52–9 provides a list of some key trading history questions.

Stock Prices

Since many lower-rated companies are over-levered, their bond performance oftentimes is highly correlated to their stock prices. In some cases, equity prices may be a leading indicator, and in other cases bond prices may lead the equity markets. In any event, equity prices (if it is public) of the specific credit, or its public peers and competitors, may have a significant impact on bond prices. As equity prices rise or fall, the equity valuation of the company changes, which essentially measures the degree of "equity cushion" on the specific credit. For example, a stock price that has declined 20% may signal that the implied asset value cushion relative to the bonds has also been dramatically reduced, thereby increasing the overall risk of the credit. If a portfolio manager is looking at two similar credits within the same industry and the same leverage ratios, he or she would rather own the company with the higher Enterprise Value-to-EBITDA valuation multiple because it ultimately implies greater asset value coverage and

EXHIBIT 52–9

Key Trading History Questions

What is the issuer's bond price history? If the bond has been volatile, in which case a higher risk premium may be more appropriate?
What is the issuer's bond spread history relative to the current spread? Is it at the tight end or wide end of its historical range? Is it aligned with the credit profile?
What is the issuer's bond spread relative to its industry or the high-yield index? How has this relationship trended over time? Is it at the tight or wide end of its historical range? Where is the price relative to where the current credit profile warrants?
What is the current spread level relative to the spread at issuance? Has it widened or tightened dramatically? Were the moves associated with a change in credit profile as opposed to more technical factors?

EXHIBIT 52–10

Enterprise Value-to-EBITDA vs. Leverage

Ent. Value as % of Total Debt:	200%	148%	135%	104%

thereby less risk (all other things being equal). In Exhibit 52–10, a company's leverage has not changed dramatically over the last four quarters, but due to a severe decline in the stock price, the enterprise valuation of the company has fallen. As a result, the enterprise value coverage of total debt has declined dramatically, and the credit risk has increased. The equity cushion is the lightly shaded area in Exhibit 52–10.

Examples such as this illustration are an important reason why portfolio managers should not take comfort in high implied levels of asset coverage based on the stock price and enterprise value. If equity investors no longer have a favorable view on the company's growth prospects, multiples may contract. Thus, it is important for the credit analysis to include alternate independent methods of asset and enterprise valuation, while monitoring and considering movements in the current public equity value. Although credit metrics may not change dramatically in the near-term, a forward-looking viewpoint of the equity valuation may be important in determining perceived enterprise value coverage and trading outlook. In Exhibit 52–10, the 104% enterprise value-to-total debt coverage in the fourth quarter (Q4) suggests that the bond requires equity-like returns as its implied asset coverage is weak.

Bank Loan Prices/CDS

Portfolio managers should monitor the price of the senior instruments in the capital structure as well as single-name CDS trends. Moreover, the lines between high-yield bonds and bank loans are increasingly blurring as the two markets

and investor bases converge. For example, if the yield on a company's term loan is too tight to the yield on its bonds, it may signify that one or both instruments are mispriced. In order to make an appropriate comparison, portfolio managers must evaluate both yields on an equivalent basis since the bank loan yield is floating rate and based on LIBOR, whereas the bonds are fixed-rate and based on comparably dated U.S. Treasuries. Monitoring CDS trends also provides a window into potential changes in market sentiment towards a particular issue. Given the illiquidity of many high-yield bonds, it is sometimes easier for investors to express their credit opinion on a given issue by trading CDS as opposed to the underlying bond. As such, market sentiment may sometimes be more quickly reflected in CDS price movement before it is evident in the bond. Evaluating and monitoring all securities within the capital structure is essential to good security selection.

Duration

Duration measures the price sensitivity to yield as well as the percentage change in price for a parallel shift in yield. The longer the duration, the more sensitive the price will be to interest rate fluctuations. Overall, bonds of equal maturity with higher yields will have shorter durations than lower yielding issues.

Duration is an important consideration in assessing relative value apart from its sensitivity to changes in underlying Treasuries and determining the appropriate level of additional compensation required for going further out on the curve. First, credit risk will naturally increase with longer dated maturities as there are many factors that can change a company's credit profile over time and have a more profound impact on a levered issuer compared with an investment-grade issuer. Second, to the extent there is near-term potential for a negative surprise, a longer duration bond should have more downside risk. As investors demand incremental yield to compensate for the risk, longer duration bonds should generally experience more downside risk.

TOP-DOWN HIGH-YIELD MARKET DRIVERS AND MACRO CONSIDERATIONS

While the bottom-up component of portfolio management should be the primary driver of security selection, it is important to incorporate a view on key macro top-down factors that will influence the markets as well as individual industries and credits. Understanding these drivers is necessary in evaluating past performance and building individual portfolios. Furthermore, macro considerations are a key component to providing the proper context for individual industry and credit allocations.

The high-yield market has eight primary drivers. The top-down (macro) component of the portfolio management process is further highlighted in Exhibit 52–11 and discussed below.

EXHIBIT 52–11

Top Down—High-Yield Market Drivers and Macro Considerations

Economic Outlook

All top-down macro views require some form of economic analysis. An assessment of current and expected future economic conditions is essential to portfolio management, as the performance of the economy has a significant bearing on the performance and profitability of the companies that make up the high-yield market. An analysis of the general economy usually begins with the business cycle. One determinant of industry allocation decisions is a forecast of whether the macro economy is improving or weakening. A forecast that differs from consensus can have a significant impact on strategy and performance. Economic indicators such as GDP, inflation, consumer sentiment, consumer spending, business investments, unemployment, housing, and ISM provide the necessary data to develop an informed viewpoint and forecast. Ideally, this data should be supplemented with primary research derived from direct management contact. Complementing economic data with primary research can provide a higher level of conviction in formulating an economic forecast. Furthermore, it may highlight risks in the consensus view and provide portfolio managers with an opportunity to add value and enhance returns. Once the economic outlook has been created, it is necessary to establish the impact of that forecast on specific industries as not all sectors are equally sensitive to the business cycle. For example, a negative economic outlook may warrant a higher weighting in defensive industries and conservatively capitalized credits. Conversely, a positive forecast would favor more economically sensitive industries and credits.

Interest-Rate Forecast and Federal Reserve Policy

Rising rates and tightening monetary policy tend to have a negative impact on fixed income investments. While high-yield has historically shown a relatively

low correlation to U.S. Treasuries as compared with many other fixed income asset classes such as investment-grade corporates, formulating an outlook on interest rates provides a framework for the construction of the portfolio. For example, if the interest rate forecast calls for a significant increase in interest rates, it may be appropriate to reduce a portfolio's exposure to low coupon, longer maturities and the most interest-sensitive lower-yielding credits. Additionally, from a credit perspective, certain industries that are highly sensitive to interest rates (such as financials) may face additional risk and technical pressure in a rising rate environment.

Equity Market Trends

Contrary to popular belief, the high-yield market has demonstrated a much higher correlation to the equity markets than to 10-year U.S. Treasuries. For the 20-year period ended February 2011, the high-yield market exhibited a –0.06 correlation to 10-year Treasuries versus a 0.58 correlation to large cap equity according to *StyleAdvisor*. Although high-yield is a fixed income vehicle, the meaningful risk premium over Treasuries absorbs much of the volatility in Treasuries to deliver more equity-like returns. As equity markets fluctuate, so does the ultimate equity cushion for debt investors. Stronger equity markets typically signify stronger outlooks and earnings momentum; however, they also signify stronger equity cushion and asset protection for bondholders. The opposite is true when equity markets are declining. These dynamics are amplified for highly levered companies. In the end, it is generally more difficult for high-yield bonds to perform well when the equity markets are declining. Portfolio managers should keep this dynamic in perspective when managing risk.

Corporate Developments

Just as corporate fundamentals drive returns on an individual issuer, broader trends in overall corporate developments influence the high-yield market as well. To illustrate, a strong equity market may drive many private high-yield companies to go public and use the proceeds to pay down debt (a positive credit event). Conversely, an overabundance of available credit may incentivize private equity sponsors to raise debt in order to fund dividends to the equity holders at the expense of existing bondholders. To the extent corporate development trends are occurring on a broader scale, it may positively or negatively impact the high-yield market as investors anticipate other issuers that are likely to undertake similar positive or negative actions.

Market Yield and Spread (Relative to Historical Averages and vs. Other Asset Classes)

In determining asset allocations for their larger, overall portfolio, investors will ultimately consider the relative yield and spread of high-yield bonds to historical averages as well as to other asset classes and investment alternatives.

This consideration provides an important perspective for high-yield portfolio managers as it is a key influence that drives overall demand in the high-yield market as well as the market technicals. In developing a relative perspective, portfolio managers should consider the following reference points and how they compare to historical ranges and averages:

- High-yield market spread over Treasuries
- High-yield market absolute yield
- High-yield market spread vs. investment-grade corporates
- High-yield market yield vs. dividend yield on the S&P 500

For example, if high-yield spreads are at all time highs, there should be strong technical pressure and ultimate demand to drive yields tighter as new buyers enter the market to take advantage of the opportunity. Additionally, if the incremental high-yield market spread over investment-grade corporates is at all-time historical tights, investors may decide that the incremental yield is insufficient, creating downside technical pressure.

High-Yield Market Supply/Demand

New issue supply and flow of funds play a meaningful role in the performance of the markets. While longer-term returns are more influenced by the overall corporate credit outlook and expected default rate, supply and demand characteristics may be difficult to forecast, but impossible to ignore. A record supply of new issuance can cause technical selling pressure on the secondary market in an otherwise fundamentally strong high-yield credit environment with low default expectations. Conversely, a lack of supply works to strengthen demand for existing issues in the secondary market and drive prices higher in a similar environment.

While new issue supply can easily be measured and monitored through multiple sources, demand is more difficult to ascertain. Although retail mutual fund flows are available on a weekly basis, they provide only a limited picture of the overall high-yield market demand. Retail mutual funds account for less than 15% of the overall high-yield market. Additionally, these funds may not accurately represent the sentiment of the larger institutional investors, which account for the majority of the high-yield market. While retail fund flows provide a window into overall demand, the largest high-yield managers with significant institutional assets can better measure demand through their own level of marketing activity and internal subscriptions/redemptions. Demand can have a significant impact on market returns, particularly in periods where new issue supply is limited.

Market Liquidity

Broker-dealers provide the liquidity needed to sustain active markets in high-yield securities. Over time, broader trends such as bank consolidation and new

foreign entrants have had an impact on market liquidity. More recently, due to the consolidation among broker-dealers which was triggered by the financial crisis, a few smaller firms focused solely on secondary trading have entered the high-yield market to populate the void created in consolidation post the financial crisis. Apart from the broader trends, the amount of capital provided to broker-dealer trading desks is a significant determinant of the ability to effectively trade in the high-yield market. For instance, a broker-dealer's senior management may decide (whether for macro concerns or company-specific circumstances) to "dial down" its risk exposure and hence limit the capital it provides to its high-yield trading desk. In turn, its traders become less willing to commit capital. As a result, investors may experience longer execution times, higher transaction costs, and greater price volatility. Market liquidity is also seasonal based on staffing and the new issue calendar. For example, late summer and periods surrounding holidays exhibit lower liquidity as broker-dealers operate skeleton crews and limit capital. Moreover, traders may be less willing to risk capital as they approach their fiscal year-end and thereby impact their year-to-date profit and loss. It is important for portfolio managers to understand both the secular and shorter-term trends that influence the ability to execute trades in the market.

Default Expectations

Since inception, the high-yield market's most important driver is default rates. In periods where default rate expectations are low, the high-yield market tends to perform well as the lower default expectations influence two important components of high-yield returns: risk premiums and default loss.

$$\text{Expected High-Yield Return} = \text{Risk-Free Rate} + \text{Risk Premium} - \text{Default Loss}$$

In an environment of lower default expectations, risk premiums as measured through credit-spreads should decline as investors are less concerned with default risk and willing to accept less yield, thereby driving bond prices up. Additionally, the lower expected default risk reduces the expected default loss, hence increasing the overall expected high-yield return. Portfolio managers can temper their portfolio risk tolerance based on their overall default expectations. For example, portfolio managers may be willing to assume more risk when the outlook for default rates are trending lower, whereas increasing default rates may warrant a more defensive posture.

PORTFOLIO CONSIDERATIONS

Portfolio considerations are the framework applied by the investment managers to ultimately decide which securities are most appropriate for inclusion in a given portfolio. They act as the filter to screen the potential investment universe

utilizing the bottom-up and top-down considerations discussed in this chapter. These portfolio considerations include:

- Client/portfolio objectives
- Risk tolerance
- Diversification
- Trading strategy
- Portfolio characteristics
- Risk controls
- Performance attribution

Client/Portfolio Objectives

Portfolio objectives are essential to providing the overall direction for portfolio construction and day-to-day investment decisions. A quote from poet Ella Wheeler Wilcox serves as a good analogy for the importance of these objectives. "One ship drives east and another drives west with the selfsame winds that blow. 'Tis the set of sails and not the gales which tells us the way to go." With respect to portfolio management, investment objectives serve as the sails to guide the portfolio in the proper direction. The most vital portfolio objectives are return target and risk tolerance. The client or portfolio manager must decide what the primary investment objective is (i.e., income generation, total return, benchmark "hugger," absolute return, or preservation of capital). Most portfolio managers have one primary objective and a secondary goal; for example, absolute total return as the primary objective and high current income as a secondary goal. The more clearly defined the objectives, the more likely the strategy will be effective and successful.

Risk Tolerance

In the universe of high-yield bonds, preserving capital and controlling risks are paramount factors in generating superior returns over a full credit and economic cycle. Calibrating the portfolio's risk tolerance goes hand-in-hand with the portfolio's investment objective.

For example, a total return strategy will necessitate a higher-risk tolerance, as managers must buy higher-yielding issues with greater risk premiums in order to achieve the high return objective. However, these greater returns and higher risk premiums will likely result in greater volatility of returns as well a higher probability of default loss. Ultimately, portfolio managers must clearly define whether their core risk tolerance is conservative or aggressive and maintain an unwavering style in the face of changing markets. Although it is feasible to beat the benchmark with a conservative strategy in a down market, or with an aggressive style in an up market, the combination of aggressive/conservative style outperforming in both bull and bear markets is extremely challenging and flawed. The lack of trading liquidity

and the unavailability of many issues in the high-yield market inhibits the ability of portfolio managers to shift between styles in a short time frame. While a portfolio manager's core strategy and risk tolerance must remain intact in order to succeed over an entire market or credit cycle, this should not preclude portfolio managers from increasing or decreasing their risk tolerance within their core conservative or aggressive strategy as market conditions change. However, these changes in risk tolerance must remain incremental as opposed to radical. Success is measured by achieving the highest risk-adjusted returns over an entire market or credit cycle.

Diversification

A key factor in reducing risk and helping to achieve return objectives is diversification. Diversification should not simply be measured by the number of investments held in a portfolio, but must be evaluated on many critical levels in order to appropriately manage and lower the overall risk. One of the most common mistakes portfolio managers make is that they "fall in love" with an industry and/or a credit and fail to properly diversify their high-yield portfolios.

There are several key factors to take into account in assessing a portfolio's diversification including:

- Issuer concentration
- Industry concentration
- Risk
- Liquidity
- Duration

Issuer Concentration

Diversification by issuer should be measured on several levels. Number of holdings and average position size are one of the most important diversification measures. Some investors may believe that a more concentrated "best ideas" approach to portfolio management (<35 issuers) will achieve the highest returns; however, it may do so at a much higher level of risk given that the most severe credit losses tend to be the unexpected ones. Conversely, some portfolio managers may believe that a large number of holdings (>200 issuers) provides greater protection against individual loss as well as smaller tracking error versus a given benchmark; however, this is typically more of an index fund approach and it is difficult to argue that a portfolio manager is adding much value in this scenario. Ultimately, a properly diversified portfolio should target position sizes of 1% to 2% on average per name in order to balance the benefits of diversification with the opportunity for greater value added. It is important to remember that larger portfolios will, by necessity, be forced to hold many more issues as their size limits the desired amount of a given issuer that can be held. In addition to the number of holdings and average position size, individual issuer limits and top 10 concentrations should also be considered. In a properly diversified portfolio, most portfolio

managers should maintain diversification percentages with limits of no more than 3% per issuer, and the portfolio's top 10 holdings should not exceed 25% of the portfolio. Portfolio managers must also make certain that their top 10 positions generate the best returns. If the top positions are underperforming, it is extremely difficult to achieve superior results.

Industry Concentration

Industry concentration levels should be held to no more than 15% to 20% and should be reserved for those industries with the strongest technical and fundamental characteristics. Additionally, the portfolio's five largest industry weightings should represent less than 50% of the total assets. Proper diversification should not only reduce a portfolio's volatility, but these weightings should help mitigate the effect of unexpected announcements by an issuer or events that affect an industry in general.

Risk

Managing risk is a critical role of the high-yield portfolio manager. Most investors look to evaluate the ratings (e.g., Moody's/S&P) distribution of the portfolio and monitor concentrations across the ratings categories. However, portfolio managers should maintain their own proprietary framework for evaluating and monitoring credit risk exposure and concentration. Another important risk factor is to identify and monitor the percentage of holdings by the lead underwriter, senior lender, and private equity sponsor. Lead underwriters and senior lenders are important because not all underwriters and lenders are equally committed to the asset class. Some underwriters-brokers are active in high-yield when there is a bull market and abandon their efforts when the market declines, leaving the purchaser holding an orphaned bond. Moreover, broker-dealers possess varying degrees of capital on their trading desks. Private equity sponsors, meanwhile, have track records that cannot be ignored. Some private sponsors are known for frequently taking major dividends out of their LBO companies, thus leaving the entities more leveraged with no benefit to the debt holders. Overconcentration in any of these factors could jeopardize performance over the long term.

Liquidity

Liquidity risk involves measuring the ability to sell a particular credit on a timely basis. If a particular high-yield bond has poor liquidity, a portfolio manager may be unable to execute a buy/sell decision. The percentage of the portfolio represented by L1, L2, or L3 liquidity ratings should be calculated and monitored. Concentration in L3 credits that trade sporadically should be a key focus as the downside risk to these holdings is amplified by their illiquidity.

Duration

For the reasons discussed above, a bond's duration is an important driver of its volatility. Portfolio managers must consider their overall exposure to both longer

and shorter duration bonds. Concentrations in either category can position the portfolio either more defensively (short duration) or more offensively (long duration). It is important to evaluate these concentrations and ensure that they are aligned with the portfolio manager's overall market outlook and portfolio objective.

Trading Strategy

Portfolio managers generally have trading styles that capture their bias toward generating short-term trading profits versus focusing on longer-term outperformance over an entire credit cycle. Given the significant transaction costs and liquidity limitations of the high-yield market, short-term trading can be costly. Furthermore, it incorporates a greater degree of risk associated with attempting to time the market that can impact long-term performance. Regardless of the type of trading strategy, portfolio managers must develop and adhere to a buy and sell discipline that reflects their style and philosophy.

Buy Discipline

In executing a buy decision, a step-by-step process is required to ensure consistency and disciplined decision making. It is critical for portfolio managers to employ a rigorous bottom-up credit/security selection process complemented by top-down macro considerations. Portfolio managers should not sacrifice this process in the name of expediency or believe they might miss a "hot" opportunity. If there is not sufficient time to complete adequate diligence on a particular issue, the investment should not be made. The optimal investment should exhibit positive characteristics across all six of the key security analysis steps discussed above and align with the overall investment objectives and risk tolerance of the portfolio. For example, portfolio managers should bifurcate the decision of whether the company is a good credit from whether the credit's bonds are attractive on a relative value basis.

Sell Discipline

Having a disciplined sale process is crucial for high-yield investing. Knowing when to sell is often times more important than knowing what to buy because losses are typically greater than gains due to the call constrained feature inherent in most high-yield bonds. The ability to execute a sell decision can separate an average portfolio manager from an extraordinary one. The three primary reasons to sell a bond are:

- Credit deterioration
- Relative value (risk/reward imbalance)
- Management drift

Strong credit analysis and continuous in-depth monitoring are key components of managing credit risk as the security analysis process does not end once a security is purchased.

Credit Deterioration. If a credit is undergoing (or forecasted to undergo) a fundamental change that may significantly increase the risk of default, the security should be sold. The more proactive a portfolio manager is, the higher the overall portfolio return as price deterioration and default loss are minimized.

Relative Value. While fundamental reasons should always be the most significant sale criteria, relative value and managing the risk/reward balance are vital factors in driving long-term returns. For example, an issuer may not necessarily be at near-term risk for default, but if its risk profile has increased (or is forecasted to increase) materially, there may be a sale opportunity if yields have not yet reflected this concern. Conversely, if a credit's yield has tightened well beyond the assessed risk, the bond should also be considered for sale. Lastly, credits that have shown significant improvement in their credit risk profile may no longer offer attractive yields. Although the credit profile may now be much stronger, an investment-grade credit profile may not be appropriate for a high-yield portfolio objective.

Management Drift. As previously discussed, the quality of the management team is a significant factor in analyzing a company. The leadership and veracity of management are paramount in making this assessment. To that end, bonds of a company where the management team deviates from its previously stated goal(s) or misleads investors must be sold. These management teams present a higher level of risk that is difficult to assess or quantify.

Red Flags

An important complement to a strong sell discipline is to have a process for uncovering potential risks that may not have been uncovered through traditional monitoring. Price drift and credit drift are two key elements to monitor. Bond prices should be monitored for declines and necessitate automatic reviews for declines of 10%. While ongoing credit analysis may not have uncovered a significant enough change in risk to justify the price movement, it is important discipline for the manager to appreciate and understand the reason for the movement. Credit drift is also an important element to monitor. For this purpose, the credit drift to monitor should be based on the proprietary method by the portfolio manager as discussed above. Reacting to changes in the major rating agencies' (e.g., Moody's and S&P) published credit ratings will invariably be a poor strategy as the market may have already priced-in the revised published credit ratings.

Portfolio Characteristics

A key element of portfolio management is monitoring and evaluating all of the portfolio's holdings. Some of the characteristics to monitor include yield-to-worst, spread-to-worst, average price, ratings, and risk, as well as the diversification considerations discussed above. Monitoring a portfolio's characteristics is an

important tool in portfolio management as it helps ensure a portfolio's holdings are in line with macro considerations and portfolio objectives as opposed to solely a result of bottom-up selection. Daily and weekly review is necessary so that portfolio managers can make informed decisions based on actual facts that reflect changes in the market rather than "seat-of-the-pants" intuition. Organized, customized, and detailed reports showing percentages and variance calculations are essential for critical decision making.

Risk Controls

One of the keys to avoiding significant losses is to establish firm risk control procedures and to develop and maintain a formal credit review process that examines the key risk factors covered in this chapter, namely credit risk, liquidity risk, and portfolio/diversification risk.

Risk controls are typically talked about but are seldom enforced in many money management organizations. Most times, organizations undertake serious, comprehensive risk controls only after a crisis. However, portfolio managers should carefully measure and monitor all three types of risk. Implementing a front-end compliance system to monitor key parameters is a critical tool for controlling risk and helping to guide a portfolio's alignment with its objectives. A front-end compliance system typically involves an integrated portfolio management and trading system in which portfolio constraints and limitations are categorized and monitored real-time. As a result, a portfolio manager is unable to enter a trade order that does not comply with the portfolio's guidelines or risk tolerances. A comprehensive front-end compliance system compares much more favorably to back-end compliance systems, which only capture violations or higher than desired exposures once a trade has already been executed. Monitoring portfolio concentrations and diversification is also another important element of risk controls.

Performance Attribution

Performance attribution is an important tool that enables portfolio managers to assess individual performance and refine the strategy. The objective is to break down the variance between a portfolio's active returns and the returns of the passive market into various segmented detail for further analysis. This analysis serves to illuminate the portfolio manager's decision-making process and reveal factors that benefited or detracted from performance for a given period. It is important to identify the many flaws inherent in utilizing a passive market index as the benchmark, particularly in high-yield, where the relative illiquidity of its underlying constituents makes the index nearly impossible to replicate in practice. Performance attribution serves as a helpful reference for portfolio managers to better understand the results of their investment decisions as well as to guide future adjustments to the portfolio.

KEY POINTS

- High-yield bonds are a unique and dynamic asset class that combine the characteristics of both fixed income securities and equities. As such, the overall approach to managing a high-yield portfolio must involve an inherent underlying focus of the three key risks: credit risk, liquidity risk, and portfolio risk.
- High-yield portfolio management incorporates three key focus areas: (1) bottom-up credit/security analysis; (2) top-down high-yield market drivers and macro considerations; and (3) portfolio considerations. All three elements are critical to effective portfolio management and the individual security selections occur at the intersection of these focus areas.
- The bottom-up credit/security analysis serves as the foundation for the investment decision. While credit analysis is arguably the most important component of the investment process, security structure/terms, covenants, trading liquidity factors and relative value ultimately determine if a "good credit" will make for a "good investment." It is important to emphasize that all of the bottom-up steps are significant in their own right, and that a favorable assessment on many of the steps may not necessarily outweigh an individual risk component that is identified in the process.
- Understanding and evaluating the top-down high-yield market drivers and macro considerations are another critical component of high-yield portfolio management. While the bottom-up component of portfolio management should be the primary driver of security selection, it is important to incorporate a view on key macro top-down factors that will ultimately drive/influence the high-yield market as well as individual industries and credits.
- Portfolio considerations are the framework applied by the portfolio manager to ultimately decide which securities are most appropriate for inclusion in a given portfolio. They create the filter that is used to screen the potential investment universe utilizing bottom-up and top-down considerations.
- The high-yield market offers favorable return opportunities, but investors must also remember the old adage: The greater the return, the greater the risks! Selecting securities with the highest yields is easy. Delivering consistent and superior risk-adjusted returns with lower volatility is what sets apart the best portfolio managers from the average.
- High-yield securities earn interest on weekends and holidays, while equities do not.

CHAPTER
FIFTY-THREE

INTERNATIONAL BOND PORTFOLIO MANAGEMENT

KARTHIK RAMANATHAN

Fidelity Management and Research Company/Pyramis Global Advisors

JAMES M. GERARD
Quantitative Research Analyst
Fidelity Management and Research Company/Pyramis Global Advisors

FRANK J. FABOZZI, PH.D., CFA, CPA
Professor of Finance
EDHEC Business School

This chapter will focus on international bond investing and the many complex factors portfolio managers need to consider when allocating assets to this sector of the fixed income market. After addressing the fundamental building blocks of international portfolio management, including currency risk and benchmark selection, the tools used to generate excess return are described, including management of currency exposure, interest rate management, and sector and security selection.

Strategic and tactical asset allocation are then defined from a fundamental-based investment approach, which leads to the central topic of portfolio construction. Portfolio construction encompasses many components and must fully address the interactions between risk factors active in international bonds. Each component of risk, including currency, interest rate, and security selection, can be broken down analytically. Since the decision to hedge currency risk is the most important determinant of risk and return facing a portfolio manager, the subject is considered in detail before turning to a discussion of the determinants of forward rates and an example of break-even analysis. The analytical foundation of these sections is the framework used by international bond portfolio managers to support investment decision-making, attribute performance, and assess portfolio exposures.

The authors would like to thank Ben Tarlow and Curt Hollingsworth of Fidelity Management and Research Company for their assistance in this chapter. In addition, Christopher B. Steward and J. Hank Lynch were significant contributors to this chapter through their work in previous editions, and sections of this chapter are adapted from those works.

While many of the examples and illustrations in this chapter apply to international investing from the perspective of a U.S. manager investing in bond markets outside the United States, it is important to keep in mind that the principles apply to any cross-border manager investing outside his domestic bond market. The same issues faced by U.S. managers regarding currency management apply to managers throughout the world when they invest in bonds in which the cash-flows are not denominated in their local currency.

Furthermore, to provide a broad overview of the many aspects of international fixed income investing in one chapter implies that many topics do not receive the depth of discussion they deserve. For example, the topic of currency management is extensive and continues to be a subject of significant debate. We provide only an overview of the fundamental principles here.

OVERVIEW OF INTERNATIONAL BOND MARKET INVESTING

As the breadth and liquidity of fixed income markets outside of the United States continues to grow, investors have increasingly included these securities in their portfolios. These allocations to international bonds offer portfolio diversification and broader opportunities for adding returns. Moreover, as the sophistication of investors evolves through broadened research coverage, robust risk analytical systems, and increased competition for returns, ignoring opportunities in this investable universe simply is not an option.

Many substantial shifts have occurred which have also increased the prominence of global bond markets. The Brady bond market, which resulted from the Latin American crisis of the late 1980s, and the Asian debt and currency crisis, which led to multiple sovereign defaults in the 1990s, gave way to the use of a common currency in Europe in 1999.

Some investors were concerned that the diversification benefits of global bond investing would be diminished by the commencement of the European Monetary Union (EMU) in 1999. But in fact the economies of continental Europe were already very closely tied together before the EMU, with most European central banks following the interest-rate policies of the German Bundesbank for several years before the move to a single currency.

Thus the impact on diversification of a global bond portfolio caused by the EMU was minimal. EMU, however, created a more robust credit market in Europe as issuers and investors, no longer confined to their home markets, access a larger, more liquid pan-European bond market. Corporate bond issuance increased sharply in Europe, and led toward a broader range of credits and instruments similar to those available in the U.S. bond market.

Just as the EMU was a major focus in the early part of the decade, the rise of Asian bond markets once again broadened the investment opportunities in global bond markets. Major sovereigns including South Korea, Mexico, and Brazil are regular issuers in the bond markets. Importantly, corporations and other

institutions within each country are available to access liquidity in both local and non-local currencies.

As the Chinese economy continues to open to investors, and liberalization of the financial system proceeds, offshore and onshore currency trading in the Chinese renminbi will continue to propel this growth. This massive growth in the local currency debt market—and the potential returns associated with both lower interest rates and currency appreciation—have given investors many reasons to enter the international bond markets.

At the same, while the benefits of investing in international bonds certainly are apparent, the risks associated with investing in these markets need to be well understood. Given the many bouts of volatility and capital losses that investors have faced in the past few decades, an allocation to this sector requires a more robust investment process. Management of an international bond portfolio poses more varied challenges than management of a domestic bond portfolio. Differing time zones, local market structures, settlement and custodial issues, and currency management all complicate the fundamental decisions facing every fixed income manager in determining how the portfolio should be positioned with respect to duration, sector, and yield-curve.

The fundamental activities in any investment management process are setting investment objectives, developing and implementing a portfolio strategy, monitoring the portfolio, and rebalancing the portfolio as needed. A well-defined, disciplined investment process is needed to address the additional complexities posed by cross-border investments versus those faced in domestic bond markets. Addressing these challenges is crucial to the investment management process.

INVESTMENT OBJECTIVES AND POLICY STATEMENTS

Most investors are attracted to global bonds as an asset class because of their historically higher returns than U.S. bonds. Others are drawn to global bonds because of their diversification value in reducing overall portfolio risk. An investor's rationale for investing in international bonds is central to developing appropriate return objectives and risk tolerances for a portfolio.

Broadly speaking, investor specifications include return objectives and risk tolerances. Each of these investment objectives has implications for the management of an international bond portfolio and should be reflected in the investment policy statement.

Global bonds initially were just a small part of an overall portfolio added for both return and diversification. As investors have gained a better understanding of international bond markets over the past two decades, allocations to the asset class have increased. The strategic asset allocation for a portfolio is made up of benchmarks that both define the asset class and provide a performance target that each investment manager strives to outperform. Return objectives often are expressed in terms of the benchmark return, for example, benchmark return plus 100 basis points over a market cycle.

The return objectives and risk tolerances will indicate not only the most appropriate benchmark, but also the most suitable investment management style. Investors who are concerned primarily with diversification may wish to place tight limits on the sizes of positions taken away from the benchmark to ensure that diversification is not weakened. A total-return-oriented investor might be far less concerned with diversification and focused on absolute return rather than on benchmark relative return.

Investment policy statements should be flexible enough to allow the portfolio manager sufficient latitude for active management while keeping the portfolio close enough to the benchmark to preserve the desired top-down asset allocation. The policy statements should address allowable investments, including:

1. The countries in the investment universe, including emerging markets
2. Allowable instruments, including mortgages, corporate bonds, asset-backed securities, and inflation-adjusted bonds
3. Minimum credit ratings
4. The currency benchmark position and risk limits
5. The use of derivatives such as forwards, futures, options, swaps, and structured notes

The time horizon for investment performance is also important. A short-term time horizon, such as a calendar quarter, may encourage more short-term trading, which could diminish the natural diversification benefit from international bonds as an asset class. Investors who emphasize the risk-reduction or diversification aspect of international bond investing should have a longer time horizon of perhaps three to five years. Since economic cycles can be prolonged, this provides enough time for a full economic cycle to add any diversification benefit.

Benchmark Selection

Benchmark selection for an international bond portfolio has many ramifications and should be done carefully. As is the case when choosing an international equity benchmark index, the choice of a pure capitalization (market value) weighted index may create a benchmark that exposes the investor to a disproportionate share in the Japanese market given the enormous size of the market relative to the investor's liabilities or diversification preferences. A global bond portfolio, which for a U.S.-based investor includes some allocation to dollar denominated domestic debt in addition to international debt, could increase the investable universe for bond managers—but returns and even diversification benefits could be reduced.

While international equity indexes chosen for benchmarks are most often quoted in the investor's local currency (i.e., unhedged), international bond benchmarks may be hedged, unhedged, or partially hedged, depending on the investor's objectives. The choice of a hedged, unhedged, or partially hedged benchmark

likely will alter the risk and return profile of the investment portfolio and should reflect the rationale for investing in international bonds.

Available Benchmarks

Benchmarks can be selected from one or a combination of the many existing bond indexes:

- Global (all countries, including home country)
- International (ex-home country)
- Government-only or GDP weighted
- Multisector or broad (including corporates and mortgages)
- Currency-hedged
- G7 only
- Maturity constrained, e.g., one to three years, three to five years, seven to ten years
- Emerging markets

Alternatively, a customized index or "normal" portfolio can be created. Some frequently used fixed income benchmarks are the Citigroup World Government Bond Index (WGBI) and the Barclays Capital Global Aggregate Bond Index. The benchmark often provides both the return objective and the measure of portfolio risk. Tracking error, the difference between the performances of the portfolio versus the benchmark, is one such measure of portfolio risk.

Benchmark Currency Position

Currency management is a matter of much debate in the academic literature. Investing internationally naturally generates foreign currency exposures. These currency exposures can be managed either passively or actively, although most global bond managers use active management to some degree.

Many managers are attracted to active currency management because of the large gains that can be attained through correctly anticipating currency movements. Since currency returns are much more volatile than bond market returns, even modest positions in currencies can result in significant tracking error. Some bond managers handle both bond and currency exposures, assuming that the same fundamental economic factors influence both bond yields and currency levels.

However, bonds and currencies frequently behave quite differently in reaction to the same external stimulus. As a result, actively monitoring and managing currency risk is in itself a significant role. Both the risks and opportunities posed by currency movements suggest that some specialization in currency is warranted, particularly as the allocation to international bond markets increases. For bond portfolios, exchange rate risk dominates overall volatility contributing up to

95% of total unhedged return volatility, explaining why practitioners tend to view hedging exchange risk in bonds as much more important.[1]

The first task is to determine the neutral or strategic foreign currency exposure appropriate for the investment objectives. Some of the academic research on currency hedging for U.S. dollar–based investors suggests that the risk-minimizing currency strategy for a global bond investor is close to a full currency hedge, with a modest long position in the U.S. dollar.[2] In fact, currency hedging is sometimes described as a "free lunch" based on the argument that currencies add only volatility, but have zero expected returns.[3]

Other studies suggest that a partially hedged benchmark offers superior risk-adjusted returns as compared with either a fully hedged or unhedged benchmark.[4] This latter research has led some to recommend a 50% hedged benchmark for either a passively managed currency strategy or as a good initial hedged position for an active currency manager. Interestingly, a 2004 survey by Russell/Mellon indicated that only about 13% of institutional investors use hedge ratios other than 0%, 50%, or 100%.[5] Once the benchmark has been selected, a suitable currency hedge position needs to be determined.

For example, a U.S. dollar–based fixed income manager whose primary goal is risk reduction might adopt a hedged or mostly hedged benchmark that has historically shown greater diversification benefit from international bonds. Despite a higher correlation with the U.S. bond market than unhedged international bonds, hedged international bonds offer better risk reduction owing to a lower standard deviation of bond returns than a U.S.-only bond market portfolio.[6]

In addition, this lesser volatility of hedged international bonds results in more predictable returns. Conversely, an investor who has a total-return objective and a greater risk tolerance would be more likely to adopt an unhedged or mostly unhedged benchmark and allow more latitude for active currency management.

From the perspective of a U.S. investor, Exhibit 53–1 shows that for the 25 year period 1985–2010, the currency component of investing in unhedged international bonds accounted for much of the total return volatility. The international bond index used is the Citigroup WGBI excluding the United States (denoted by "non-U.S. WGBI").

EXHIBIT 53–1

Hedged and Unhedged Returns: 1985–2010

		Non-U.S. WGBI	U.S.	Non-U.S. HEDGED	50% HEDGED
1985–2010	Return	9.57%	7.71%	7.14%	8.46%
	Volatility	10.04%	4.95%	3.25%	5.97%
	SR	0.51	0.66	0.84	0.67
1985–1998	Return	13.23%	9.75%	9.11%	11.28%
	Volatility	10.85%	4.96%	3.63%	6.49%
	SR	0.66	0.77	0.89	0.82
1999–2010	Return	5.46%	5.37%	4.90%	5.26%
	Volatility	8.92%	4.88%	2.62%	5.19%
	SR	0.30	0.54	0.83	0.49

Data obtained from Fidelity Investment Management and Research, Citigroup World Government Bond Index data.

Investing in international bonds on a hedged basis reduced the return in most periods but also substantially reduced the return volatility. As can be seen in Exhibit 53–1, over the 25-year history of the WGBI, hedged international bonds returned less than unhedged international bonds and even lagged the U.S. component of the WGBI slightly. However, the volatility of the hedged non-U.S. WGBI was lower than that of the unhedged index and that of the U.S. component.

To compare returns on a risk-adjusted basis, we can use the Sharpe ratio.[7] Despite the higher return of the unhedged non-U.S. WGBI, its risk-adjusted return was lower than the hedged index and the U.S. bond component alone for the whole 1985–2010 period.

As noted earlier, using a 50% hedged portfolio offers a compromise in that its return is virtually midway between the return of the unhedged non-U.S. WGBI and the U.S. bond component, with substantially lower volatility than the unhedged index, giving it a higher Sharpe ratio than the unhedged index. Of course, the relative performance of the hedged versus the unhedged index depends on the performance of the home currency (here the U.S. dollar), which can experience long cycles of strength or weakness.

The advantage of using a partially hedged benchmark versus a fully hedged or fully unhedged benchmark is illustrated in a mean-variance framework in Exhibit 53–2. We began by assuming that we could invest in any combination of the four asset classes highlighted in Exhibit 53–1. We used the (unweighted)

7. The Sharpe ratio measures returns in excess of the risk-free rate per unit of standard deviation. In the Exhibits, the risk-free rate is taken to be the three-month Treasury bill rate.

EXHIBIT 53–2

Risk-Return for Unhedged and Hedged International Bond Portfolios (U.S. Investor Perspective) 1985–2010 Historical Returns

Data obtained from Fidelity Investments, Citigroup World Government Bond Index data.

sample returns, variances, and covariances of the four portfolios to construct the overall efficient frontier, and overlaid two subfrontiers that constrain the holdings to U.S. bonds + WGBI ex-U.S. (hedged), and U.S. + WGBI ex-U.S. (50% hedged).

From the standpoint of the U.S.-based investor, it is clear that adding an increment of 50% hedged global bonds substantially increased the overall portfolio return over the period, while keeping total portfolio risk very close to that of the U.S.-only portfolio. Indeed, in the neighborhood of U.S.-only portfolio risk, the U.S. + WGBI ex-U.S. (50% hedged) combination turned out to be very close to optimal.

It is important to keep in mind that these historically constructed efficient frontiers are more of an illustration than a guide to long-run portfolio construction. For example, the last row of Exhibit 53–1 shows how much the relationship between the hedged and unhedged portfolios have moved with time. The impetus for this move, of course, has been the secular global rates rally that has been in progress for most of the WGBI's history. Also note that the financial crisis of 2007–2009 greatly upset traditional correlations among all asset classes, including currencies and interest rates.

Returns of partially hedged U.S.-based global bond portfolios have also benefited from the trend of depreciation in the U.S. currency relative to other major global currencies, particularly since the establishment of the EMU. With the convergence of global rates, and the likelihood of future—possibly significant—rate increases, global portfolio managers are going to have to adapt their country allocation and currency risk strategies. The sections to follow outline the analytical foundations of strategy formation.

Risk Limits

Many investment guidelines will include explicit risk limits on bond and currency positions as well as duration and credit risk. Exposure limits can be expressed either as absolute percentages or as weights relative to a benchmark. Increasingly, tracking error limits also have been used to set risk limits in investment guidelines.

Limits on investment in countries outside the benchmark should be specified at the outset. Despite the pitfalls of using duration to measure interest-rate risk across countries,[8] risk limits on duration are nonetheless useful and should be established. The range of allowable exposures is often wider for bond exposures than for currency exposures.

Credit-risk limits, usually a minimum-weighted-average credit rating from the major credit rating agencies, and limits on the absolute amount of low- or non-investment-grade credits also should be included. Apart from default risk, the illiquidity of lower-rated securities may hamper a manager's ability to alter exposures as desired. In the past, this was due to the lack of a liquid corporate bond market in many countries and the relative illiquidity of Eurobonds compared with domestic bond markets.

DEVELOPING A PORTFOLIO STRATEGY

Once the investment policy statement is established, the portfolio manager needs to develop a portfolio strategy appropriate to the investor's objectives and risk tolerances. Just as in many other areas of investment management, portfolio managers often subscribe to different management styles or investment disciplines.

The performance of most portfolio managers is judged against the benchmark return, not absolute returns.[9] There are a number of means by which portfolio managers can add to returns; however, the bulk of excess returns relative to the

8. The use of duration as a measure of interest rate risk when investing in a single bond market has merits; however, such a measure of duration in a portfolio of international bonds is not relevant. A simultaneous *and* identical parallel shift in interest rates in each of the countries in which the portfolio manager has invested would be necessary for the duration metric to be properly applied. As a result, an overall duration measure in an international bond portfolio is not applicable.

9. In the international bond management business, however, absolute return is gaining in prominence as a performance measure, particularly when overall interest rates are at low levels.

benchmark come from broad bond market and currency allocation decisions. A disciplined investment approach based on fundamental economic factors or market indicators of value facilitates the market and currency selection process. Once again, because of the historically high volatility of currency returns, the approach to currency management is a primary concern.

Styles of International Bond Portfolio Management

The challenges faced by international fixed income managers are different from those facing domestic fixed income managers. First, the international fixed income portfolio manager must operate in the U.S. bond market plus 10–20 other markets, each with their own market dynamics. Second, changes in interest rates generally affect different sectors of the U.S. bond market in much the same way (with the exception of mortgage-backed securities), although the magnitude of the changes may vary. However, international bond markets may move in different directions depending on economic conditions and investor risk tolerances.

International bond managers also use one or more different management styles. These can be divided into four general categories: the experienced trader, the fundamentalist, the black box, and the chartist.

The *experienced trader* uses his or her experience and intuition to identify market opportunities. The experienced trader tends to be an active trader, trying to anticipate the next market shift by international fixed income investors such as hedge funds, pension funds, and central banks. The basis for these trades is derived from estimates of market positioning and risk tolerances and supported by observation of market price movements and flow information. The experienced trader is often a contrarian, looking to profit from situations in which many investors may be forced to stop themselves out of losing positions.

The *fundamental style* rests on a belief that bonds and currencies trade according to the economic cycle. Sector rotation within corporate bonds also will be affected by the economic cycle, as different sectors perform relatively better at different points in the cycle. Some of these managers believe that the economic cycle can be forecast and rely mostly on economic analysis and forecasts in selecting bond markets and currencies. These managers tend to have less portfolio turnover because the economic fundamentals have little impact on short-term price movements. "Bottom-up" security selection in corporate bonds could also be characterized as a fundamentalist approach, even though it rests on issuer-specific fundamental analysis rather than on broad economic fundamentals.

The *black-box approach* is used by quantitative managers who believe that computer models can identify market relationships that people cannot. These models can rely exclusively on economic data, price data, or some combination of the two. Quantitative managers believe that using computer models can create a more disciplined investment approach that, because of other managers' emotional attachment to positions, their lack of trading disciplines, or their inability

to process more than a few variables simultaneously, will provide superior investment results.

Some investors called *chartists,* technical analysts, or technicians, may rely primarily on technical analysis to determine which assets to buy or sell. Chartists will look at daily, weekly, and monthly charts to try to ascertain the strength of market trends or to identify potential turning points in markets. Trend-following approaches, such as moving averages, aim to allow the portfolio manager to exploit market momentum. Countertrend approaches, such as relative-strength indexes and oscillators, try to identify when recent price trends are likely to reverse.

Very few international bond portfolio managers rely on only one of these management styles, but instead use some combination of each. Investment managers who rely on forecasts of the economic cycle to drive their investment process will from time to time take positions contrary to their medium-term strategy to take advantage of temporary under- or overvaluation of markets identified by technical analysis or estimates of market positions.

Even "quant shops" that rely heavily on computer models for driving investment decisions will sometimes override the model's decisions and look to other management styles to add incremental returns. Regardless of the manager's investment style, investment decisions must be consistent with the investor's return objectives and risk tolerances and within the investment guidelines.

International bond portfolio managers would do well to maintain a disciplined approach to buy and sell decisions. This would require each allocation away from the benchmark to have a specified price target (or more often yield spread or exchange-rate level) and stated underlying rationale. Depending on the management style, the size of the position should reflect the strength of the investor's conviction or model's signal.

As long as the investment rationale that supported the initial decision remained unchanged, the position would be held or potentially increased if the market moves in the opposite direction. Each trade should be designed with consideration for the relevant bond yield or exchange rate's behavior through time. For example, an exchange rate that exhibits a tendency to trend will require a different buy and sell discipline than one that tends to consistently revert back to an average level.

SOURCES OF EXCESS RETURN

The baseline for any international bond portfolio is the benchmark. However, in order to earn returns in excess of the benchmark, after management fees, the portfolio manager must find ways to augment returns. These excess returns can be generated through a combination of five broad strategies:

1. Currency selection
2. Duration management/yield-curve plays
3. Bond market selection

4. Sector/credit/security selection
5. Investing in markets outside the benchmark (if permitted)

Each of these strategies can add to returns; however, currency and bond market selections generally provide the lion's share of returns. We discuss each of these sources of excess return below.

Currency Selection

Most investment guidelines allow for some active management of currency exposures. The attraction of active currency management is strong because potential gains are so large. Since the volatility of currency returns is generally higher than that of bond market returns, the incremental returns gained from currency exposures must be evaluated relative to the additional risk incurred.

For an active currency management strategy to consistently provide superior risk-adjusted performance, a currency forecasting method is required that can predict future spot rates (i.e., future exchange rates) better than forward foreign exchange rates (i.e., rates that can be locked in today using the market for forward contracts). Forward foreign exchange rates are not forecasts of future spot foreign exchange rates, but are determined by short-term interest-rate differentials between currencies.

Academic studies have shown that several strategies have been successful in generating consistent profits through active currency management. The fact that forward foreign exchange rates are poor predictors of future spot exchange rates is well established. Historically, discount currencies (i.e., those with higher interest rates than the investor's local currency) have depreciated less than the amount implied by the forward rates, providing superior returns from holding unhedged positions in currencies with higher short-term interest rates. Overweighting currencies with high real interest rates versus those with lower real interest rates also has been shown to provide incremental returns.[10]

In addition, some currency movements are not a random walk but exhibit serial correlation (i.e., currency movements have a tendency to trend).[11] In a market that tends to trend, simple technical trading rules may provide opportunities for incremental currency returns.[12] These findings in several academic studies demonstrate that excess currency returns can be generated consistently, providing

10. See Gastineau, "The Currency Hedging Decision," pp 13–14.
11. One suggestion as to why currency markets trend is that central banks attempt to smooth foreign exchange-rate movements through intervention. Thus, because central bank participation in the foreign exchange market is not motivated by profit, their actions keep the market from being truly efficient. See Robert D. Arnott and Tan K. Pham, "Tactical Currency Allocation," *Financial Analysts Journal* (May–June 1993), pp. 47–52.
12. See Richard M. Levich and Lee R. Thomas, "The Merits of Active Currency Risk Management: Evidence from International Bond Portfolios," *Financial Analysts Journal* (September–October 1993), pp. 63–70.

a powerful incentive for active currency management. At the same time, as currency markets have become more transparent and liquid, and these strategies have become more broadly known, the efficacy of standard techniques will likely diminish—requiring the evolution of more sophisticated approaches.

Duration Management

Although closely aligned with the bond market selection decision, duration management also can enhance returns. Bullet versus barbell strategies in a curve-steepening or -flattening environment within a particular country's bond market can enhance yield and total return. In addition to these strategies, which are also available to managers investing in their domestic bond market, the international fixed income portfolio manager has the option of shifting duration between markets while leaving the portfolio's overall duration unchanged.

Tools to manage duration in international bond portfolios have become more widespread over the past few decades. The interest-rate swaps market is generally very liquid across international bond markets and used extensively by institutional investors to manage rate risk. Interest-rate futures, available in most markets, offer a liquid and low-cost vehicle for changing duration or market exposure quickly. More liquid government bond issues and the development of strip markets (which separate government bond cash-flows into individual interest and principal payments) also assist portfolio managers when managing duration exposure.

Bond Market Selection

Excess returns over the benchmark index from overweighting the best-performing bond markets can be extremely large. International bond portfolio managers apply many techniques to identify these bond markets, including macroeconomic forecasts, quantitative models, and sovereign risk. Relative value opportunities can result from market dislocations, illiquidity, and lack of full information, resulting in attractive entry points for bond managers.

Sector/Credit/Security Selection

Some global bond indexes include only government bonds, but others, such as the Barclays Global Aggregate and the Citigroup Global Broad Investment Grade Indexes, incorporate other instruments, including corporate bonds and mortgages. As corporations look to access liquidity beyond their domestic investor base and issue in international markets, the overall corporate bond market has become an even more attractive source of return for portfolio managers.

Those managers who typically apply a core "bottom-up" research approach to identifying value base on credit fundamentals can now focus on an even broader universe of securities. Similarly, mortgage bonds, high-yield debt, covered bonds, and asset-backed securities can offer incremental opportunities for

return. In certain environments in which markets are trendless or the rate environment is fairly stable, sector and security selection can be drivers of return versus duration management.

Investing in Markets Outside the Index

If allowed by investment guidelines, allocating assets to markets outside the index can enhance returns significantly without dramatically altering the risk profile of the portfolio. For example, a portfolio manager who uses the Citigroup World Government Bond Index as his or her benchmark would be taking out-of-benchmark bets if an allocation were made of corporate credit or mortgage debt.

The process for selecting an out-of-index market is similar to that followed by an active manager for a domestic bond portfolio when deciding whether or not to construct a portfolio with allocations different from the benchmark index and whether or not to invest outside the index. The manager will assess the potential performance on a total-return basis of the markets outside the index relative to that of the markets to be underweighted in order to allocate funds to out-of-index markets. An international bond portfolio manager, however, also must take into account the effect of currency movements and hedging decision of an investment outside or within the index.

THE FUNDAMENTAL-BASED INVESTMENT APPROACH

The portfolio strategy is often composed of a medium-term strategic allocation and a shorter-term tactical allocation. The strategic allocation is composed of positions held for one to three months or longer designed to take advantage of longer-term economic trends. A fundamental-based approach is used to develop the portfolio's strategic allocation. The investment style used in the fundamental-based approach is, of course, the fundamental style, but also can be combined with a quantitative or black-box style to forecast relevant strategic factors.

The tactical allocation generally relies on technical analysis or flow information to identify shifts in market prices that are likely to occur within a few days to several weeks. Tactical allocations can be driven by expectations of a reversal in a recent price trend or continued price momentum. The experienced trader, black-box, and chartist investment styles most often use technical analysis combinations in their tactical allocation decisions.

The strategic decision of which bond markets and currencies to overweight usually begins with an economic outlook and bond and currency forecasts in each of the markets considered for investment. The long-run economic cycle is closely correlated with changes in bond yields, and trends in both the economic cycle and bond yields tend to persist for a year or longer. The potential returns that can be achieved by correctly forecasting economic growth or turning points in the economic cycle are significant. As a result, major financial firms and asset managers allocate many resources to these duties.

Forecasting interest rates, however, is extremely difficult. Academic literature generally holds that interest-rate forecasts are unable to generate consistent risk-adjusted excess returns. This is partly so because market prices can deviate substantially over the short term from the level consistent with the economic fundamentals. Economic fundamentals affect bond and currency prices over the medium to long term.

Also, the volatile nature of certain economic data series may result in exaggerated market reactions to individual data releases that may be different from the actual trend in the economy. These deviations may persist for several months until either the initial figure is revised or several subsequent data releases reveal the error in the initial interpretation.

The creation of an independent economic outlook can be useful in several ways. First, it can help to identify when market interpretations of the economic data are too extreme or add value through correctly anticipating economic shifts not reflected in the market consensus.

Second, since it is often not absolute changes in interest rates but changes in interest rates relative to other markets that determine the margin of performance in international fixed income investing, an independent economic outlook does not require accurate growth forecasts for each individual market but only economic growth differentials to be able to add value. Whether the portfolio will invest in U.S. bonds or not, the large influence of the U.S. dollar and the Treasury market on foreign markets underlines the importance of an independent outlook on the U.S. economy.

Thus the economic outlook forms the foundation for the *strategic* allocation to bonds and currencies. An economic outlook for each country should be constructed to assist in ranking the relative attractiveness of markets. However, even though economic fundamentals in a particular country may be extremely bond supportive, bond prices may be too high to make it an attractive investment.

Likewise, bonds are sometimes excessively cheap in countries with poor economic fundamentals and hence may provide an attractive investment opportunity. Thus the economic outlook must be compared with either consensus economic forecasts or some market value measure to identify and rank attractive investment opportunities.

The strategic allocation decision regarding which markets to overweight or underweight relative to the benchmark is thus a complex interaction of expected returns derived from assessing economic trends and technical and value factors. Each set of variables is defined and explored below, beginning with the fundamental factors used to create the economic outlook.

The main fundamental economic factors are cyclic economic indicators, inflation, monetary policy, fiscal policy, debt, balance of payments, and politics. Each factor needs to be evaluated against market expectations to determine its likely impact on bond prices and currency rates. Each of these factors is covered in considerable detail in books on macroeconomics and international economics.

Identifying trends in economic fundamentals can help to identify attractive investment opportunities in markets, but some yardstick to measure relative value

is needed. Determining relative value is highly subjective. Three relatively objective value measures include real yields, technical analysis, and market sentiment surveys.

A *real yield* is the inflation-adjusted rate of return demanded by the market for holding long-term fixed income securities. Real yields can quickly be eroded by sustained inflation. Real yields are affected by a variety of factors, including supply and demand for capital as well as inflation expectations. Real yields are simply nominal bond yields minus expected inflation; however, expected inflation is often difficult to quantify.

Some countries, including the United States, have inflation-indexed bonds that pay a real rate of interest above the inflation rate. These bonds not only provide investors with some protection against a surge in inflation but also offer a means of gauging investor inflation expectations.[13]

Nominal bond yields deflated by current inflation, although not a precise measure of the market's real interest-rate premium, are easily measurable and still can provide some useful insight into bond valuation. Real yields can be compared across markets or against their long-run averages, such as 5 or 10 years, in each market. The usefulness of real yields as a measure of relative value has diminished as global inflation rates have converged to very low levels.

Technical analysis can be as simple as drawing a trend line on a chart or as complex as calculating the target of the third impulse wave of an Elliott wave analysis. In addition to valuing bonds and currencies, technical analysis can be used to value everything from stocks to gold to pork bellies. What all technical analysis has in common is that it tries to predict future prices solely from examining past price movements. Most technical analysis models fall into one of two camps: trend following or countertrend. The former tries to identify trends that should persist for some period of time, and the latter attempts to predict when a recent trend is likely to change.

Market sentiment can be used as a contraindicator of value in the following way. A heavy overweight of a particular country's bond market implies that fewer managers are likely to add to that market, and more managers, at least eventually, are likely to sell. Market sentiment can be estimated by investor sentiment surveys or by estimates of investment flows. Historic trends, as well as the overall levels, should be taken into account when assessing market sentiment.

For example, an indication that managers are underweighting Japanese bonds might lead some to conclude that Japanese bonds are due for a rally. Sentiment surveys, however, may not capture all market participants and therefore simply offer yet another metric for the international bond portfolio manager.

---

13. Nominal yield-to-maturity is composed of a real yield and an inflation expectations component (yield-to-maturity = real yield-to-maturity + expected inflation-to-maturity). The nominal government bond yield and the real yield offered by inflation-indexed debt of the same maturity can be used to calculate the expected inflation rate to the maturity, sometimes called the break-even inflation rate.

PORTFOLIO CONSTRUCTION

Translating the strategic outlook into a portfolio allocation requires a framework for assessing expected returns against incremental portfolio risk. Returns can be separated into three components: excess returns on bonds, excess returns on currencies, and the short-term risk-free interest rate. This component methodology can assist in identifying where market prices are most out of line with the economic outlook and whether bond market currency exposures should be hedged or be unhedged.

Components of Return

To explain the total return components of an international bond portfolio[14] we will use the following notation. We will let "home currency" mean the currency of the manager. Thus, for a U.S. manager, it is U.S. dollars. For a Japanese portfolio manager it is yen. In the notation, the subscript H will denote home currency.

We will let "local currency" be the currency of the country where the manager has invested and use the subscript L to denote the local currency. Thus, to a U.S. portfolio manager, yen would be the local currency for bonds purchased in the Japanese bond market and denominated in yen, while for a Japanese portfolio manager, U.S. dollars would be the local currency for bonds purchased in the United States and denominated in U.S. dollars.

The expected total return of an unhedged international bond portfolio in terms of the home currency depends on three factors:

1. The weight of each country's bonds in the overall portfolio
2. The expected bond market return for each country in local currency
3. The expected exchange-rate percentage change between the home currency and the local currency

Mathematically, the expected total return of an unhedged bond portfolio in terms of the home currency can be expressed as follows:[15]

Total expected portfolio return in manager's home currency

$$= W_1 \times (r_1 + e_{H,1}) + W_2 \times (r_2 + e_{H,2}) + \ldots + W_N \times (r_N + e_{H,N}) \qquad (53\text{–}1)$$

where

N = number of countries whose bonds are in the portfolio
W_i = weight of country i's bonds in the portfolio (i = 1, 2, … , N)

14. The structure of this discussion is taken from Brian D. Singer and Denis S. Karnosky, *The General Framework for Global Investment Management and Performance Attribution* (Charlottesville, VA: The Research Foundation of the Institute of Chartered Financial Analysts, 1994). The notation used is consistent with that of the authors.
15. The relationship in Eq. (53–1) is approximate because bond market and currency returns of a foreign investment are more accurately expressed as the compounded gain of the two components: $(1 + r_i) \times (1 + e_{\$,i}) - 1$.

r_i = expected bond return for country i in local currency (i = 1, 2, … N)
$e_{H,i}$ = expected percentage change of the home currency with country i's local currency

We will refer to $e_{H,i}$ as the *currency return*.

The expected portfolio return as given by Eq. (53–1) is changed to the extent the manager alters currency exposures relative to the country distribution of the underlying bond exposures. A common instrument used to alter exposure to exchange rates is a currency forward contract. The relationship among the spot exchange rate, the interest rates in two countries, and the forward exchange rate on a currency forward contract is called *interest-rate parity*.

This extremely important relationship says that a manager, after hedging in the forward exchange-rate market, will realize the same domestic return whether investing domestically or in a foreign country. The arbitrage process that forces interest-rate parity is called *covered interest arbitrage*.

It can be demonstrated that the forward exchange rate between an investor's home currency, denoted H and the currency of country i, is equal to

$$F_{H,i} = S_{H,i}\,(1 + c_H)\;1 + c_i \tag{53–2}$$

where

$F_{H,i}$ = forward exchange rate between investor's home currency and the currency of country i
= spot (or cash) exchange rate between investor's home currency and the currency of country i
c_H = short-term interest rate in the home country which matches the maturity of the forward contract
c_i = short-term interest rate in country i which matches the maturity of the forward contract

c_H and c_i are called the *cash rate*. The cash rate is generally the Eurodeposit rate (i.e., offshore deposit rate) for funds deposited in that currency which matches the maturity of the forward contract. Euro deposit rates are available for U.S. dollars and most other major currencies, including for euro-denominated deposits.

By rearranging the above terms in Eq. (53–2), the forward exchange rate discount or premium (or the percentage change of the forward rate from the spot exchange rate), denoted by $f_{H,i}$, approximately equals the differential between the short-term interest rates of the two countries. That is[16]

$$f_{H,i} = \frac{f_{H,i} - S_{H,i}}{S_{H,i}} \approx c_H - c_i \tag{53–3}$$

16. Equation (53–2) assumes that exchange rates are quoted in "direct terms," i.e., the value of the home currency for one unit of the local currency, though quote conventions vary by market. Over-the-counter forward contracts use market convention, most of which for the U.S. dollar are in indirect terms (local currency units per one dollar). Using indirect terms, the forward discount or premium in Eq. (53–3) becomes $f_{H,i} = c_i - c_H$. To avoid the complexities of compounding, the time period is assumed to be one year.

That is, for the return on cash deposits to be equal in both currencies, the lower-interest-rate currency must appreciate to the forward foreign exchange rate.

The forward rate can also be expressed in "points" or the difference between the forward and spot rate $F_{H,i} - S_{H,i}$. When interest rates are lower in the foreign country (i.e., the forward points are positive), the forward foreign exchange rate trades at a premium.

The Currency Hedge Decision

If a global bond portfolio is fully hedged, the portfolio return of Eq. (53–1) changes. Specifically, if the manager hedged the currency exposure in all countries using currency forward contracts, the total return for a fully hedged portfolio into the home currency can be expressed as follows:

Total expected portfolio return fully hedged into investor's home currency

$$= W_1 \times (r_1 + f_{H,1}) + W_2 \times (r_2 + f_{H,2}) + \ldots + W_N \times (r_N + f_{H,N}) \qquad (53\text{–}4)$$

where $f_{H,i}$ is the forward exchange-rate discount or premium between the home currency and country i's local currency. That is, instead of being exposed to some expected percentage change of the home currency to country i's currency, the manager will have locked in the percentage change of the forward exchange rate from the spot exchange rate (the forward discount/premium) at the time of the hedge.

What will determine whether or not the manager will hedge the exposure to a given country's exchange rate using a currency forward contract? The decision is based on the expected return from holding the foreign currency relative to the forward premium or discount. That is, if the manager has a high level of conviction that the percentage return from exposure to a currency is greater than the forward discount or premium, then the manager will not use a forward contract to hedge the exposure to that currency.

Conversely, if the manager has a high level of conviction that the currency return will be less than the forward discount or premium, the manager will use a forward contract to hedge the exposure to a currency.

In a case in which the manager believes that the percentage return from exposure to a currency will be greater than the forward discount or premium, the unhedged return for country i can be expressed as

$$\text{Unhedged expected return for country } i,\ R_{H,i} = r_i + e_{H,i} \qquad (53\text{–}5)$$

In a case in which the manager believes the currency return will be less than the forward discount or premium, we can express the hedged return for a country in terms of the forward exchange rate between the home and local currencies using the interest rate parity relationship. As Eq. (53–3) showed, the forward premium or discount is effectively equal to the short-term interest rate differential; thus

$$f_{H,i} = c_H - c_i$$

By substituting this relationship into Eq. (53–4) for the forward hedge, the equation for an individual country's hedged return HR is

$$\text{Hedged expected return for country } i,\ HR_{H,i} = r_i + f_{H,i} \approx r_i + c_H - c_i \qquad (53\text{–}6)$$

There remain, however, two further hedging choices for the manager: *cross-hedging* and *proxy hedging*.

Cross-Hedging

Cross-hedging is a bit of a misnomer because it does not reduce foreign currency exposure but only replaces the currency exposure to country i's currency with currency exposure to country j's currency.

For example, suppose a U.S. manager has an unwanted currency exposure in country i that arose from an attractive bond investment in country i. Rather than hedging with a forward contract between U.S. dollars and the currency of country i and eliminating the foreign currency exposure, the manager elects to swap exposure in country i's currency for exposure to country j's currency.

This is accomplished by entering into a forward contract that delivers the currency of country j in exchange for the unwanted currency exposure of country i. The manager might undertake a cross-hedge if there is an expectation of weakening in the home currency, coupled with the view that country j's currency will outperform country i's.

When there is a cross-hedge, the hedged return for country i, $HR_{H,i}$, in Eq. (53–6) can be rewritten as follows:

$$\text{Cross-hedged expected return for country } i,\ CR_{H,i} = r_i + f_{j,i} + e_{H,j}$$

where $f_{j,i}$ is the forward discount or premium between country j and country i.

This expression says that the cross-hedged return for country i depends on:

1. the expected bond return for country i
2. the currency return locked in by the cross-hedge between country j and country i
3. the currency return between the home currency and country j

We can rewrite the preceding equation in terms of short-term interest-rates as given by interest-rate parity. That is, for $f_{j,i}$, we substitute $c_j - c_i$. Doing so and rearranging terms gives

$$\text{Cross-hedged expected return for country } i,\ CR_{H,i} \approx (r_i - c_i) + (c_j + e_{H,j}) \qquad (53\text{–}7)$$

Equation (53–7) says that the cross-hedged expected return for country i depends on:

1. the differential between country i's bond return and country i's short-term interest rate
2. the short-term interest rate in country j
3. the currency return between the home currency and currency j

Proxy Hedging

Proxy hedging keeps the currency exposure in country i, but creates a hedge by establishing a short position in country j's currency. Why would a manager want to undertake a proxy hedge?

This strategy would normally be considered only where the currencies of country i and country j are highly correlated, and the hedge costs in country j are lower than in country i. A proxy hedge also can represent a bullish view on the home currency, with a more negative view on country j's currency than country i's currency.

When there is a proxy hedge, the hedged return for country i, $HR_{H,i}$, in Eq.(53–6) can be rewritten as follows:

Proxy-hedged expected return for country i, $PR_{H,i} = r_i + e_{H,i} + f_{H,j} - e_{H,j}$

where $f_{H,j}$ is the forward discount or premium between the home country and country j.

Notice that in this equation there is still the exposure to the exchange rate between the home currency and currency i. The proxy hedge comes into play by the shorting of the currency return between the home currency and currency j.

Based on interest-rate parity, we can replace $f_{H,j}$ with the difference in short-term interest rates, $c_H - c_j$, to get

Proxy-hedged expected return for country i, $PR_{H,i} \approx r_i + e_{H,i} + c_H - c_j - e_{H,j}$

This is equivalent to (adding and subtracting the country i short interest rate c_i):

Proxy-hedged expected return for country i,

$$PR_{H,i} \approx (r_i - c_i) + (c_i + e_{H,i}) + [(c_H - c_j) - e_{H,j}] \tag{53–8}$$

Equation (53–8) states the expected return for country i using proxy hedging depends on:

1. the differential between the bond return for country i and the short-term interest rate for country i
2. the short-term interest rate for country i adjusted for the currency return for country i relative to the home currency
3. the differential in the short-term interest rates between the home currency and country j adjusted for the short currency position in country j

Recasting Relationships in Terms of Short-Term Interest Rates

When we substituted short-term interest-rate differentials for the forward premia or discounts earlier, it becomes apparent from Eqs. (53–6), (53–7), and (53–8) that the difference in return among hedging, cross-hedging, and proxy hedging is entirely due to differences in short-term interest rates and currency exposure. This

is also true for the unhedged return for a country, as given by Eq. (53–5). This can be seen by simply rewriting Eq. (53–5) as follows:

Unhedged expected return for country i, $R_{H,i} = (r_i - c_i) + (c_i + e_{H,i})$

The unhedged expected return is thus equal to:

1. The differential between the bond return in country i and the short-term interest rate in country i
2. The short-term interest rate in country i adjusted for the currency return

These equations show how integral the short-term interest-rate differential is to the currency hedge decision. This means that:

1. The short-term interest-rate differential should relate to the currency decision
2. Bond market returns should be calculated as an excess return, that is, less the local short-term interest rate

This can be made explicit by adding and subtracting the home currency short-term interest rate to the four return relationships—unhedged, hedged, cross-hedged, and proxy-hedged. By doing so, this allows the forward premium $f_{H,i} = c_H - c_i$ to be inserted into the currency term, giving

Unhedged expected return for country i,

$$R_{H,i} = c_H + (r_i - c_i) + (e_{H,i} - f_{H,i}) \tag{53–9}$$

Hedged expected return for country i,

$$H_{RH,i} = c_H + (r_i - c_i) \tag{53–10}$$

Cross-hedged expected return for country i,

$$CR_{H,i} = c_H + (r_i - c_i) + (e_{H,j} - f_{H,j}) \tag{53–11}$$

Proxy-hedged expected return for country i,

$$PR_{H,i} = c_H + (r_i - c_i) + [(e_{H,i} - e_{H,j}) - f_{j,i}] \tag{53–12}$$

From Eqs. (53–9) through (53–12), we see the return for each strategy can be divided into three distinct return components:

Component 1. The short-term interest rate for the home currency (c_H)

Component 2. The excess bond return of country i over the short-term interest rate of country i ($r_i - c_i$)

Component 3. The excess currency return, unhedged, cross-hedged, or proxy-hedged

The first two components, c_H and $r_i - c_i$, are the same for each strategy. The excess currency return (the third component) is the currency return in excess of the forward

premium (or discount) and forms the basis of the currency hedging decision. (We will illustrate this below.) The bond purchase decision is purely a matter of selecting those markets which offer the best expected excess return ($r_i - c_i$) and the bond and currency allocation decisions are entirely independent.

In a sense, the hedged expected return can be considered the base expected return because it is a component of the unhedged, cross-hedged, and proxy-hedged expected returns. Thus the excess currency returns in the third component are assessed to see if they can add any value over the baseline hedged expected return. This method of analyzing sources of return, in effect, treats bond and currency returns as if they were synthetic futures or forward positions.

It is important to note that only the hedged position eliminates all currency risk, and the only position that has a known return over the investment horizon. The cross-hedge substitutes one currency exposure for another but maintains foreign currency exposure. The proxy hedge leaves the portfolio exposed to "basis" risk if the proxy hedge currency appreciates relative to the investment currency.

Adjusting Bond Yields for Coupon Payment Frequency

In the United States and most other dollar bloc countries, coupon payments are made semiannually. There are other markets that follow this practice. Computing the yield for a semiannual-pay bond can be accomplished using two steps. First, the semiannual interest rate that will make the present value of the semiannual cash-flows equal to the price plus accrued interest is determined. Second, since the interest rate is semiannual, it is annualized by multiplying by 2. The resulting annualized yield is referred to as a bond-equivalent yield.

In European markets (except for the United Kingdom and Italy), coupon payments are made annually rather than semiannually. Thus, the yield is simply the interest rate that makes the present value of the cashflows equal to the price plus accrued interest. No annualizing is necessary.

The yield quoted in terms of the home market's convention for payments is called the *conventional yield*. In countries where coupon payments are made annually (in Germany, for example), the conventional yield is simply the annual yield.

Despite the limitations of yield measures, managers compare yields across market sectors and between countries. Holding aside the problem of potential changes in exchange rates, yield comparisons begin by adjusting conventional yield (i.e., the yield as quoted in the home market) to be consistent with the way the yield is computed for another country.

For example, a French government bond pays interest annually, while a U.S. government bond pays interest semiannually. If the U.S. government bond yield is being compared to a French government bond yield, either (1) the U.S. government bond yield should be adjusted to the yield on an annual-pay basis, or (2) the French government bond yield should be adjusted to a yield on a bond-equivalent yield basis.

The adjustment is done as follows: Given the yield on an annual-pay basis, its bond-equivalent yield (i.e., a yield computed for a semiannual-pay bond) is computed as follows:

$$\text{Bond-equivalent yield of an annual-pay bond} = 2[(1 + \text{yield on annual-pay bond})^{0.5} - 1]$$

For example, suppose that the conventional yield on a French government bond is 4.55%. The bond-equivalent yield is then 4.50%:

$$2[(1 + 0.0455)^{0.5} - 1] = 0.0450 = 4.50\%$$

Notice that the bond-equivalent yield of an annual-pay bond is less than that of the conventional yield.

To adjust the bond-equivalent yield of a semiannual-pay bond to that of an annual-pay basis so that it can be compared to the yield on an annual-pay bond, the following formula can be used:

$$\text{Yield on an annual basis of a bond-equivalent yield} = (1 + \text{bond-equivalent yield}/2)^2 - 1$$

For example, suppose that the conventional yield of a U.S. government bond is 4.20%. The yield on an annual-pay basis is

$$(1 + 0.0420/2)^2 - 1 = 0.0424 = 4.24\%$$

Notice that the yield on an annual-pay basis will be greater than the conventional yield. Yield spreads are typically computed between the yield of a particular bond and that of a benchmark. The U.S. Treasury yield-curve and the Euro swap market are the two most common benchmarks used.

Forward Rates and Break-Even Analysis

As explained earlier, there are various methods of evaluating relative value in international bond markets. Before these can be translated into a market allocation, a manager must compare their strategic outlook to that which is already priced into the market. This can be accomplished by either converting the economic outlook into point forecasts for bond and currency levels or looking at the forward rates implied by current market conditions and comparing them with the economic outlook.

Bond and currency break-even rates, the rate at which two investments produce identical total returns, are usually calculated versus a benchmark market return over a specific time horizon. A large yield spread between two markets implies a larger "cushion" (the required spread widening to equate total returns in both markets or the break-even rate) over the investment time horizon.

Comparing forward interest rates can be instrumental in identifying where differences between the strategic outlook and market prices may present investment opportunities. Forward interest rates use the shape of the yield-curve to calculate implied forward bond rates and allow a quick comparison of what is

required, in terms of yield shifts in each market, to provide a return equal to the short-term risk-free rate (a zero excess return). This would correspond to a bond excess return of zero in Eqs. (53–9) through (53–12), or $(r_i - c_i) = 0$.

Forward interest rates represent a break-even rate not across markets but within markets. The strategic bond allocation then can be derived by increasing exposure to markets in which the expected bond return over the short-term interest rate is most positive—that is, in which the expected bond yield is furthest below the forward yield. Forward rate calculators are available on systems such as Bloomberg.

The forward foreign exchange rate represents a break-even rate between hedged and unhedged currency returns, as shown previously in the components of return analysis. In terms of Eqs. (53–9), (53–11), and (53–12), currency excess return is zero when the percentage change in the currency equals the forward premium or discount. Since forward foreign exchange rates are determined by short-term interest-rate differentials, they can be estimated from the interest rates on deposits, specifically, Euro deposit rates, as in Eqs. (53–2) and (53–3), which can be obtained easily from market data services such as Bloomberg and Reuters.

Break-even analysis provides another tool for estimating relative value between markets. Because the prices of benchmark bonds are influenced by coupon effects and changes in the benchmark, many international fixed income traders and portfolio managers find it easier to keep pace with changes in yield relationships than price changes in each market. A constant spread between markets when yield levels are shifting, however, may result in a variation in returns as differing benchmark bond maturities and coupons result in a wide spread of interest rate sensitivity across markets. Thus market duration must be taken into account when determining break-even spread movements.

To illustrate this and show how break-even analysis is used, the yield spread between the 10-year U.S. and Japanese government bonds on December 3, 2002 was 322 basis points, providing Japanese investors who purchased the U.S. benchmark Treasury with additional yield income of 80 basis points per quarter. This additional yield advantage, however, can be eliminated by the spread widening substantially less than the 80 basis points. The widening can occur in one of the following two ways:

- Yields in Japan can decrease, resulting in price appreciation of the Japanese government bond
- Yields in the United States can increase, resulting in a price decline of the U.S. Treasury bond

Of course, a combination of the two also can occur. To quantify the amount of spread widening that would erase the yield advantage from investing in a higher yielding market, we need to conduct a break-even analysis.

It is important to note this break-even analysis is not a total-return analysis; it applies only to bond returns in local currency and ignores currency movements. This break-even analysis is effective in comparing bond markets that share a common

currency, as within the Euro zone; however, currency must be taken into account when applying break-even analysis to markets with different currencies.

The additional yield advantage in the preceding example is erased if the U.S. dollar depreciates by more than 0.80% during the quarter. Below we illustrate how a hedged break-even analysis can be calculated using hedged returns or simply the forward foreign exchange premium or discount between the two currencies.

The duration of the Japanese bond at the time of this analysis was 9.4. This means that for a 100 basis point change in yield, the approximate percentage price change for the Japanese bond would be 9.4%. For a 50-basis-point change in yield, the percentage price change for the Japanese bond would change by approximately 4.7%. We can generalize this as follows:

$$\text{Change in price} = 9.4 \times \text{change in yield}$$

If we let W denote the spread widening, we can rewrite the preceding equation as

$$\text{Change in price} = 9.4 \times \text{W}$$

We want to determine the amount of yield movement in Japan that would exactly offset the yield advantage of 0.80% from investing in U.S. bonds. Thus we need to calculate what decline in Japanese bond yields would generate exactly 0.80% in price appreciation to make the Japanese investor indifferent between the two investments (ignoring any potential currency movements).

Thus the equation becomes

$$0.80\% = 9.4 \times \text{W}$$

Solving for W,

$$\text{W} = 0.80\%/9.4 = 0.085\% = 8.5 \text{ basis points}$$

Therefore, a spread widening of 8.5 basis points due to a decline in the yield in Japan would negate the additional yield from buying the U.S. Treasury issue. In other words, a change in yields of only 8.5 basis points is needed in this case to negate the three-month yield advantage of 80 basis points.

We refer to this yield spread change as the break-even spread movement. Note that the break-even spread movement must (1) be related to an investment horizon and (2) use the higher of the two countries' modified durations. Using the highest modified duration provides the minimum spread movement that would offset the additional yield from investing in a higher-yielding market.

Thus, in our example, the three-month break-even spread movement due to Japanese yields is 8.5 basis points, meaning that it is the spread movement due to a drop in Japanese rates by 8.5 basis points that would eliminate the three-month additional yield from investing in U.S. Treasury bonds. The break-even spread movement using the 8.1 duration in the U.S. would have been 9.9 basis points (0.8/8.1 = 9.9); a difference of only 1.4 basis points.

The break-even spread movement just described completely ignores the effect of currency movements on returns. It also ignores the implied appreciation

or depreciation of the currency reflected in the forward premium or discount. If we subscribe to the methodology of attributing cash returns to the currency decision and measuring bond market returns as the local return minus the cash rate, the results of the break-even spread movement analysis on a hedged basis may be quite different.

We can easily calculate the hedged break-even spread movement by adding in the forward foreign exchange discount or premium. At the time of this break-even analysis, three-month interest rates were 0.0675% in Japan and 1.425% in the United States.

With this information, we can obtain the embedded forward rate using Eq. (53-3); that is,

$$f_{¥,\$} = c_{¥} - c_{\$} = (0.0675\% - 1.425\%)/4 = -0.34\%$$

The expected hedged return over the three-month period, assuming no change in rates, is the sum of the nominal spread differential (0.80%) and the forward premium (–0.34%), or 0.46%. Thus the break-even spread movement on a hedged basis is a mere five basis points (0.46% = 9.4 × W) instead of the 8.5 basis points of potential widening calculated on a local currency basis.

Consequently, a Japanese investor would have to expect either that spreads would not widen by more than five basis points or believe that the dollar would depreciate versus the yen by less than the embedded forward rate to make the trade attractive. Because currency hedge costs (i.e., the forward premium or discount) are determined by short-term interest rates, the break-even spread movement on a hedged basis always will be smaller when hedging a currency with higher short-term interest rates.

Alternatively, we could use Eq. (53–10) to calculate the expected hedged return to a yen-based investor over a three-month period and compare it to the return on a Japanese 10-year bond over the same period. In order to do so, it is first necessary to adjust the U.S. government bond yield (which is quoted on a bond-equivalent yield basis) to an annual-pay yield basis because the Japanese yield is based on an annual basis. The conventional yield of 4.20% for the U.S. government bond was 4.24% on an annual-pay basis. Assuming no change in rates, the expected hedged return is

$$[(r_{\$} - c_{\$}) + c_{¥}]/4 = [(4.24\% - 1.43\%) + 0.07\%]/4 = (2.88\%)/4 = 0.72\%$$

and the expected Japanese bond return is (1.02%/4, or 0.26%).

Thus the expected return on a hedged basis is 0.44%, which is close to the 0.46% in the first answer that we calculated.

Sector and Security Selection

Once the bond market allocation decisions have been made and the optimal currency, duration, and yield-curve profile selected for each market, the actual portfolio needs to be constructed through the purchase or sale of individual securities.

Many international bond investors prefer to trade only benchmark issues because they are more liquid than other similar-maturity bonds. This can sometimes lead to a "hump" in the yield-curve as investors prefer a certain issue or maturity sector. The same phenomenon can result from a squeeze of certain issues in the repo market or short-term demand imbalances for bonds deliverable into short bond futures positions.

Sector selection involves choosing a certain asset class within the fixed income universe that may be undervalued relative to other opportunities. For example, a portfolio manager looking at opportunities in the United Kingdom may favor domestic corporate bonds over government issued gilts. Such a view need not be confined to just one country however. The same investor, for example, who believes corporate bonds in the United Kingdom look more attractive compared with those issued in Italy may overweight the former versus the latter. Identifying these opportunities requires a thorough analysis of relative sector specific dynamics such as the impact of interest rates, growth prospects and other idiosyncratic risks. Moreover, this sector expertise needs to be translated across regions.

Security selection is yet another source of potential return in a global bond portfolio and necessitates a comprehensive credit research team. This team should be able to dissect credit securities across countries and financial markets. Assembling such a team with deep knowledge of local market conditions and factors affecting credit quality is in itself a significant endeavor. However, portfolio managers who have access to such a bench of credit analysts could generate returns above and beyond those managers focused only on active currency, interest rates, and sectors management.

As an example, a portfolio manager could choose to overweight certain industry groups, such as financial institutions, within a specific country. For example, as a result of global credit research recommendations and perspectives, the portfolio manager may favor certain financial companies in Japan over similar institutions in the United Kingdom. By overweighting the debt of these specific Japanese financial institutions, the portfolio manager potentially can attain better returns. Such a strategy once again requires robust risk management systems to minimize idiosyncratic risk; however, achieving these incremental gains can boost the overall performance of the portfolio's return, particularly in an environment in which rates and/or currencies are range bound.

Similarly, a portfolio manager with a view that gross domestic product (GDP) will grow faster in Japan versus Germany may favor the debt of a consumer goods companies in the former rather than the latter. Consistent with this view, the portfolio manager may choose to make an outright purchase of debt issued by a specific Japanese consumer goods company. Another potential approach would be to overweight the debt issued by the Japanese consumer goods company while underweighting the debt of the German consumer goods company. A portfolio manager with a greater risk appetite and strong conviction with regard to his team's views may even choose to outright sell the debt issued by the German consumer goods company.

Taxation issues also need to be taken into account when selecting individual bonds for purchase. For example, some markets have tax systems that encourage investors to hold lower-coupon bonds; hence, certain bonds will tend to trade rich or cheap to the curve depending on their coupon. In markets that impose withholding taxes on coupon payments, international fixed income portfolio managers often minimize their tax liability by replacing a bond that is near its coupon date with another bond of similar maturity. Market anomalies also can arise from differing tax treatment within markets.

Hence, international bond portfolio managers have many avenues to generate return, including active currency and interest rate management as well as sector-specific investments. Moreover, with the assistance of a strong global research team, these portfolio managers also may be able to identify specific industry sectors or specific issuers that may increase portfolio returns. Given the breadth of the global fixed income universe, all of these asset allocations can be made relative to interest rate, sector, and security-specific opportunities in other countries. At the same time, while international bond portfolio managers have many potential opportunities to generate returns, they do face many more risks than domestic bond managers. To successfully navigate the international bond market, these portfolio managers need to develop a strong risk management framework and embrace a disciplined investment strategy that can be employed on a global basis.

KEY POINTS

- Global bond exposure, a growing segment of overall portfolio asset allocation, is for both return and diversification purposes.
- Investment policy statements should address allowable investments, including the countries in the investment universe, the securities permitted for portfolio inclusion, the currency benchmark position and risk limits, the time horizon, and the use of derivatives.
- Benchmark selection for an international bond portfolio has many ramifications and should be done carefully because it provides both the return objective and the measure of portfolio risk.
- Investing internationally naturally generates foreign currency exposures that can be managed either passively or actively based on risk guidelines and return objectives.
- Using a 50% hedged portfolio generally offers a compromise in that its return is virtually midway between the return of the unhedged non-U.S. WGBI and the U.S. bond component with substantially lower volatility than the unhedged index, giving it a higher Sharpe ratio than the unhedged index.

- International bond managers also use one or more different management styles, which generally can be divided into four general categories: the experienced trader, the fundamentalist, the black box, and the chartist.
- Excess returns in international bond portfolios are driven by a combination of five broad strategies: currency selection, duration management/yield-curve plays, bond market selection, sector/credit/security selection, and out of benchmark investments.
- Factors such as economic growth, monetary policy, fiscal policy, and politics all play a role in making the strategic asset allocation decisions in a fundamental-based approach to international bond management.
- Other tools used to identify attractive investment opportunities include measures such as real yields, technical analysis, and market sentiment surveys.
- The expected total return of an unhedged international bond portfolio in terms of the home currency depends on three factors: the weight of each country's bonds in the overall portfolio, the expected bond market return for each country in local currency, and the expected exchange-rate percentage change between the home currency and the local currency.
- In a hedged international bond portfolio, the expected portfolio return is changed to the extent the manager alters currency exposures using instruments such as currency forward contracts relative to the country distribution of the underlying bond exposures.
- Other hedging choices for the manager include *cross-hedging* and *proxy hedging*.
- The difference in return between hedging, cross-hedging, and proxy hedging is entirely due to differences in short-term interest rates and currency exposure.
- Bond and currency break-even rates, the rate at which two investments produce identical total returns, are usually calculated versus a benchmark market return over a specific time horizon.
- Comparing of forward interest rates can be instrumental in identifying where differences between the strategic outlook and market prices may present investment opportunities.
- Once the bond market allocation decisions have been made and the optimal duration and yield-curve profile selected for each market, the overall portfolio structure needs to be constructed through the purchase or sale of individual securities which are in or out of benchmark.

CHAPTER
FIFTY-FOUR

FIXED INCOME TRANSITION MANAGEMENT

ANANTH MADHAVAN, PH.D.
Managing Director
BlackRock

DANIEL GALLEGOS
Director
BlackRock

Investing is a dynamic process. Portfolios shift over time, as a result of market movement or investment changes. Transition management refers to the process by which institutional portfolios are efficiently and cost-effectively reallocated.

Moving from the current allocation to the desired allocation presents a risk/cost tradeoff similar to the risk/return tradeoff familiar in investment management. In this way, portfolio transitions closely resemble short-term investment assignments. Transition management focuses on identifying and implementing a strategy to arrive at the target portfolio most efficiently, given the investor's risk/cost priorities.

Transitions can be triggered by a variety of events, most commonly changes in fund management (such as replacing a poorly performing investment manager), shifts in asset allocation (equity to fixed income), investment style (index to active), and benchmark universe (S&P 500 to Russell 1000).[1] Transitions range in complexity from a straightforward liquidation of fund assets to a complete portfolio restructuring encompassing multiple asset classes and countries.

Historically, transitions were often viewed as an operational issue, a secondary consequence of a larger investment decision. It was not uncommon for the fiduciary to direct the previous investment manager to liquidate the original (legacy) portfolio and have the new manager invest the cash proceeds in the desired (target) portfolio, thereby incurring round-trip transaction costs. Greater awareness of transaction costs, together with concerns about fiduciary responsibilities, has led

1. Other events, such as fund flows, consolidations, or mergers can also induce transitions.

institutional investors to increasingly use transition managers for portfolio restructurings.[2]

Yet, despite the importance of portfolio transitions, many investment professionals do not fully understand the complexities involved. Indeed, some transitions can experience significant volatility of outcomes in the space of a few days. This is especially important, as we explain below, for fixed income transitions where assets are often illiquid and markets are opaque. In this chapter, we explain the process of transition management and the appropriate balance of portfolio risk and transaction costs. We introduce cost and risk measures, discuss the unique features of fixed income transitions, and illustrate several of these factors in a case study.

BASICS OF FIXED INCOME TRANSITIONS

Before turning to a more in-depth consideration of risk and cost, it is worth outlining the basics of transition management, including a chronology of events, the types of risk that must be managed for all transitions (regardless of asset class), and a discussion of what makes fixed income transitions unique.

Chronology of Transition Events

The fixed income transition management process is made up of various distinct phases: manager selection, communication of objectives, determination of trade list, pre-trade analysis, creation of trade strategy, execution, and post-trade reporting. A description of these phases and their importance to the overall event are provided below.

1. *Manager selection:* After the decision to use a transition manager is made, the fiduciary or plan sponsor undertakes a due diligence process to select the manager. Investors typically seek the same level of market expertise, risk management, liquidity, operational infrastructure, and fiduciary oversight during transitions that they have come to expect from asset managers. Transitions that are not properly managed can result in significant underperformance and excessive fee-taking. Managers can be broker-dealers, custodians, or specialized transition managers; they vary in terms of their access to liquidity, trading skill, and risk control. Successful transition managers actively mitigate transition risk by minimizing market impact and opportunity cost

2. Ideally, investors should use a transition manager when the expected cost of not using a transition manager is greater than the transition management fees. This is usually the case for significant portfolio restructurings, situations in which the investor is concerned about obtaining superior execution quality and/or maintaining a given market exposure, particularly complex transitions (e.g., portfolios containing significant exotic or odd-lot securities), and highly volatile environments.

during trading, and by carefully controlling transaction costs such as commissions and spreads.

2. *Communication of objectives:* The transition manager must understand the client's motivation and desired timing for the transition, as well as their tolerance for risk and cost. The client may also have benchmark preferences for measuring cost (previous closing price, volume-weighted average price, etc.). Other factors that could affect the transition are also communicated to the transition manager at this time (regulatory prohibitions against internal crossing, among others).
3. *Determination of trade list:* Having established the legacy and target portfolios, the manager determines the common holdings that can be transferred in-kind between them (meaning that the underlying securities retained for the target portfolio are transferred directly, cost and risk free, rather than liquidated). The remainder must be traded. Essential operational steps and necessary legal and administrative issues also must be resolved at this point.
4. *Pre-trade analysis:* The manager uses pre-trade analytical models to assess the liquidity characteristics of the trade list (focusing on breakdowns by side, order size, sector, industry, country, etc.) and estimate total portfolio trading costs and likely variation in those costs. Managers also use risk models, typically fundamental multifactor models, to estimate the tracking error between the legacy and target portfolios.
5. *Creation of trading strategy:* Strategies can vary widely in terms of aggressiveness and complexity. A common strategy is simply to trade a constant fraction of the list over the transition, with the objective of executing at the volume-weighted average price (VWAP) for the period. In some cases, managers may use optimization tools to determine the dynamic trading strategy most appropriate for the transition. The transition duration, cost estimate, and dispersion in outcomes are communicated to the client *before* the transition begins, to form an objective benchmark for measuring the eventual outcome of the transition.
6. *Execution:* The manager then executes the trades in a manner consistent with the strategy formulated in the previous step, while also making adjustments necessitated by changing market conditions. Actual transitions can range in duration from a single day to over a month, depending on the client's objectives and complexity of the trades.
7. *Post-trade reporting:* The manager provides a detailed report to the client, with particular attention to the realized costs (including commissions, bid/ask spreads, and market impact costs) relative to the pre-trade estimate. It is important to note that transition performance is measured from the date on which the transition manager is able to start executing the restructuring (as opposed to the client's decision date) to truly reflect the transition manager's efforts.

Types of Transition Risk

A poorly managed portfolio restructuring—one that does not assess and address all risks properly—has the potential to erase an entire year of investment returns. There are four types of risk that must be managed across all transitions:

- *Exposure Risk:* Also known as *investment risk,* exposure risk is associated with factors that can have a negative effect on portfolio value. Transition managers use a variety of processes (various types of trade analytics), tools (portfolio optimizers, for example), and market expertise (including broker-dealer relationships) to help minimize exposure risk.
- *Execution Risk:* After the transition strategy has been set, there is still risk of implementing the plan with suboptimal results, particularly for illiquid asset classes. Key to sourcing liquidity is understanding the intrinsic value and structural nuances of each security being traded.
- *Process Risk:* Communication gaps and unchecked assumptions contribute to process risk, which results in additional transition costs. Rigorous and detailed methodology helps minimize this risk.
- *Operational Risk:* This is the risk that operational details, such as account setup and reconciliation, are overlooked or delayed. Transition managers create transparent and auditable reporting to reduce this possibility.

Each type of risk should be managed comprehensively throughout every transition. For fixed income portfolios in particular, there are several market factors—discussed below—that make these transitions especially challenging.

Uniqueness of Fixed Income Transitions

The nature of fixed income securities makes transitions involving this asset class rather unique relative to those of other asset classes, especially equities. Several factors are particularly relevant here in terms of cost and risk:

- *Market Structure:* Fixed income securities are typically not traded on an open exchange, so pricing lacks uniformity and transparency.[3] Varied maturities, volatility due to interest rate instability, nuances in investment characteristics, and currency fluctuations pose significant challenges for fixed income portfolio transitions, which are well beyond the scope of most equity transitions. In terms of the framework above, the absence of

3. Exceptions include fixed income futures contracts and transactions on certain electronic exchanges such as Market Axxess, and Tradeweb, typically in liquid government issues.

last trade reporting (e.g., a ticker tape for most fixed income securities) makes it very difficult to measure actual costs using the shortfall framework, let alone make accurate estimates before the transition begins.

- *Price Discovery and Liquidity:* Market structure and the complexity of instruments also affect the trading strategy and execution. Unlike equities, price discovery and liquidity sourcing are particularly critical for fixed income transitions. The absence of a single, centralized bond exchange and the proliferation of instruments necessitate the use of available sources of liquidity to achieve best execution. Thus, transition managers actively pursue counterparties across multiple platforms. Transition managers benefit from long-standing relationships with broker-dealers around the world to maximize trading opportunity and achieve better execution.
- *Types of Exposure Risk:* It is difficult to gauge the active risk (tracking error) of a complex bond portfolio and, hence, to implement an optimal trading strategy, as discussed above. The typical fixed income transition may be subject to multiple dimensions of risk, including:
  - Rate risk
  - Volatility risk
  - Credit-spread risk
  - Idiosyncratic risk

Fixed income transition managers develop and implement techniques, metrics, and reporting tools specific to fixed income securities that are designed to achieve the investors' target portfolio with the lowest risk possible.

TRANSITION METRICS AND OBJECTIVES

With an understanding of the challenges specific to fixed income transitions, we can now turn our attention to an in-depth discussion of risk and cost. A variety of metrics for cost and risk are commonly used to measure the performance of a transition. In this chapter, we focus on implementation shortfall and tracking error. The first, implementation shortfall, measures the amount by which the legacy portfolio's return falls short of the target portfolio's return. This metric allows an investor to evaluate how their portfolio performed during the restructuring period. The expected implementation shortfall is established prior to the transition and decomposed into return factors, when the transition manager formulates the restructuring strategy.

For similar insights, we focus on risk in terms of portfolio tracking error (TE), which refers to the absolute difference between the returns of the legacy and target portfolios. With these metrics in hand, we then formally define the transition manager's objective.

EXHIBIT 54–1

Transition Timeline

To illustrate why these measures are most appropriate, a more formal statement is useful. Let N denote the number of assets in the universe defined by the union of the legacy and target portfolios, and let Ω denote the $N \times N$ variance-covariance matrix of asset returns. From the viewpoint of the transition manager, the process begins on day t_0 when the transition manager is first in a position to begin trading the legacy portfolio.[4] We denote by V_0 the initial value of the portfolio at this date. Trading need not occur immediately. For example, transition managers might postpone trading to source liquidity or unexpected delays might arise. At calendar time t_b (where $t_0 \leq t_b$), the manager actually begins executing the transition through trading. Let T denote the duration of the transition, which we think of as days but could also represent hours or other intraday periods. Trading occurs in waves on each day (indexed by $k = 1,\ldots,T$), and the transition is completed on day $t_1 = t_0 + T$. The timeline for the transition is illustrated in Exhibit 54–1.

Denote by L the $N \times 1$ vector of asset holdings of the legacy portfolio, where each row represents the shares held of the asset, and similarly define by Q the holdings in the target portfolio. We denote by h_L and h_Q the corresponding vectors of holdings (weights) in the legacy and target portfolios, where the i-th element of the holding vector represents the portfolio weight in asset i as a fraction of total portfolio value.

Active risk is defined as the distance between the legacy and target portfolios, captured as

$$\sigma_{L,Q} = \sqrt{(\mathrm{h}_L - \mathrm{h}_Q)'\Omega(\mathrm{h}_L - \mathrm{h}_Q)}. \tag{54–1}$$

Note that when the transition is a straight liquidation to cash, we have $\mathrm{h}_Q = 0$, the null vector, and the active risk is simply the standard deviation of the legacy portfolio; that is, $\sigma_L = \sqrt{\mathrm{h}_L{}'\Omega\mathrm{h}_L}$. Similarly, when the transition is a cash investment, $\mathrm{h}_L = 0$, and the active risk is the standard deviation of the target portfolio, $\sigma_Q = \sqrt{\mathrm{h}_Q{}'\Omega\mathrm{h}_Q}$. Thus, the active risk for non-rebalance transitions (either into or

4. The planning process begins before this date, with the selection of the manager and several other operational steps, but our focus is on performance during the actual transition process. For data on actual transition costs, see Anna Obizhaeva, "Information vs. Liquidity: Evidence from Portfolio Transition Trades," Working Paper, Sloan School of Management, MIT, Cambridge, MA (2008).

out of cash) will typically be higher than for transitions in which at least some holdings are in common.

Defining Transition Costs

The trade list is simply the $N \times 1$ vector of shares,

$$X = (Q - L) \tag{54–2}$$

with the convention that positive elements represent purchases and negative elements represent sales.

Total transaction costs incorporate explicit costs (commissions, taxes, and fees) and implicit costs (bid/ask spreads, market impact).[5] In a transition, unlike most institutional trading, orders are (nearly) always completed, so opportunity costs from failing to execute generally are not a factor.[6] In keeping with previous research, costs are expressed relative to the pre-trade benchmark (strike) price. Formally, for asset $i = 1,\ldots, N$, the realized transaction cost is

$$C_i = \frac{\sum_{k=1}^{T}(p_{i,k}^{e} + \varphi_{i,k})x_{i,k}}{p_i^b \sum_{k=1}^{T} x_{i,t}} - 1 \tag{54–3}$$

where

Dates $k = 1,\ldots, N$,

$p_{i,k}^{e}$ is the execution price,

$x_{i,k}$ is the signed trade size,

$\varphi_{i,k}$ represents the explicit trading cost (with the sign convention that costs are positive for buys and negative for sells), and

p_i^b is the benchmark or strike price against which costs are measured.

For purchases, we expect costs to be positive; for sales, the figure should be negative. Dollar implementation shortfall is the total cost measured relative to a benchmark price struck at time t_b is $C(t_b) = \sum_{i=1}^{N}(p_i^b \sum_{i=1}^{T} x_{i,k})C_i$. Throughout this chapter, we use implementation shortfall to refer to the total realized costs relative to initial transition value $c(t_b) = C(t_b)/V_0$.

The return of the target portfolio over the period of the transition (from t_0 to t_1) is denoted $r^Q(t_0, t_1)$; this is the return earned by an investor who already

5. Andre Perold, "The Implementation Shortfall: Paper Versus Reality," *Journal of Portfolio Management* (Spring 1988): 4–9.

6. Donald B. Keim and Ananth Madhavan, "Anatomy of the Trading Process: Empirical Evidence on the Motivation for and Execution of Institutional Equity Trades," *Journal of Financial Economics* (March 1995): 371–398.

held the target portfolio at the beginning of the transition. The actual return of the legacy (restructured) portfolio from t_0 to t_1 is defined as

$$r^L(t_0,t_1) = \frac{\left(V_T^L - V_0\right)}{V_0}$$

The final value of the legacy portfolio once the transition is complete is the end of period share holdings (L + X) evaluated at prices at the end of the transition, less the net cash-flows from trading. Using the definition of costs, it is straightforward to show that

$$r^Q(t_0,t_1) - r^L(t_0,t_1) = c(t_b) + r^L(t_0,t_b) \tag{54–4}$$

where $c(t_b)$ is the total implicit and explicit trading cost as a fraction of portfolio value (given a benchmark struck just prior to trading), and $r^L(t_0,t_b)$ is the return on the legacy portfolio from the time the transition began, a timing cost. In cases in which the transition begins without delay, the benchmark price is struck at time t_0, so $p_i^b = p_{i,0}$, and we see that the implementation shortfall cost is the difference between the actual return of the transition (legacy) account compared with the return on the target fund, had the transition been implemented instantaneously at no cost. This explanation shows why implementation shortfall is the right measure of costs. It accurately captures the slippage between the legacy and target portfolios, reflecting all costs incurred during the transition.[7]

Transition Tradeoffs

Having defined formally both risk and cost, we can now specify possible transition objective functions. As mentioned above, the transition manager and client jointly determine the trading strategy with the client's objectives in mind. Typically this involves a tradeoff between cost and active risk. Formally, predicated upon a horizon of T trading days, the optimal transition strategy can be defined as the set of trading waves that minimize, in expectation, a convex combination of $c(t_b)$ and $\sigma_{L,Q}$, with weight λ. Formally,

$$\min_{\{X_1,\ldots,X_T\}} E_0[(1-\lambda)c(t_b) + \lambda\sigma_{L,Q}] \tag{54–5}$$

subject to

$$\sum \mathrm{X}_k = \mathrm{X}$$

7. The industry has yet to adopt a standard approach to performance measurement in transitions. Many costs are hidden (e.g., when a custodian systematically executes foreign exchange trades at prices worse than prevailing market prices) and transition manager revenues are not transparent (e.g., the manager charges commissions on the other side or engages in proprietary trading). The T Standard is an industry initiative to create uniform standards for measuring transition performance using the implementation shortfall approach.

Both cost and risk depend on the particular waves chosen. For example, if λ is very high and the trading strategy is very aggressive, the bulk of the trade list may be completed in the first or second wave (recall, there could be multiple waves in a day), which might lead to high trading impact but low tracking error.

What is the optimal solution to this objective? Various heuristics are commonly employed but often fail to actually minimize costs. Some managers believe that maximizing the crossing rate will always minimize market impact and, hence, costs. However, this fails to account for the additional risk caused by prolonging the transition, which is a common problem in many fixed income securities in which crossing is a low-probability event. Another common strategy (usually referred to as the VWAP strategy because it is associated with a trading benchmark of the volume-weighted average price) is simply $X_t = X/T$, where the order is broken up equally over time. The VWAP strategy may not, however, be the optimal solution (even if $\lambda = 0$) and it may not minimize costs.

Rather, the optimal solution can be found using stochastic dynamic programming, given assumptions about the evolution of prices and liquidity. This forward-looking approach is based on the idea that the solution (or policy function) at any point throughout the trading session k, must still be optimal for the remaining program.[8] Using a forward-looking approach also allows the transition manager to capture variations in liquidity or volatility (the key drivers of cost) that are known to occur over the period of the transition. For example, a transition executed during a period with highly anticipated macroeconomic events (e.g., earnings season) can take into account likely spikes in volatility and volume. This approach can also provide a tradeoff between cost and risk for various λ, allowing the client to visualize the alternatives. The dynamic programming approach requires a considerable degree of confidence in the input estimates, which may not always be the case for less liquid assets. In those cases, the transition manager can use their experience and judgment (sometimes guided by the formal analysis) to correctly sequence the trades in accordance with client objectives. Whether the strategy is specified formally or informally, however, the basic tradeoffs outlined above are present in every transition.

Implementation Shortfall Example

To illustrate the concepts above, consider a $1 billion international equity transition. A state retirement system sought to rebalance its international positions by reallocating the legacy portfolio to two new managers. The total transition period was eight days, of which the trading period was five days. Forecast costs for the trade list were 0.51%. The transition manager used proprietary analytical tools to match and split out buys and sells, then utilized a transaction cost model to predict the (half) bid/offer spread plus estimated market impact. The manager then added

8. See Robert Almgren and Neil Chriss, "Optimal Execution of Portfolio Transactions," *Journal of Risk* 3 (Winter 2000): 5–39. See also Dmitri Bertsemas Dmitri and Andrew W. C. Lo, "Optimal Control of Liquidation Costs," *Journal of Financial Markets* 1 (February 1998): 1–50.

estimated commissions, fees, and taxes to this figure to determine the total forecast cost, which became the benchmark for evaluating the transition. Annualized active risk (i.e., the tracking error between the legacy and target portfolio) was 3.50%. Based on this figure, the estimated risk over the trading period was 0.39% (with 250 trading days annually, $0.495\% = 3.5\%\sqrt{\frac{5}{250}}$). This figure was used to determine upper and lower bounds for the transition shortfall.

Ex post, the actual average active risk was 0.38%, implying that the manager traded more aggressively to reduce the risk in the early stages of the transition. The legacy portfolio performance over this period was 0.69%, while the target portfolio returned 1.40% over the transition; applying Eq. (54–4) yields a total implementation shortfall of 0.71% (1.40%–0.69%). The realized trading shortfall was 0.58% (market impact of 0.42% and commissions and fees of 0.16%), in line with the pre-trade forecast. Timing costs accounted for 0.14%, reflecting outperformance of the target portfolio relative to the legacy portfolio in the three days before trading started.[9] Overall, although total costs were slightly higher than predicted (7 bps), the outcome was within the range of possible outcomes communicated to the client before the transition, which signifies the success of this transition.

The Risk/Cost Tradeoff Revisited

Fixed income and equity market transitions are similar in terms of the risk/cost tradeoff outlined above, but there are material differences in how these transitions are executed. Like most U.S. equities, the majority of investment-grade debt can be liquidated or purchased within a short period of time. However, additional costs are normally incurred when selling or buying too quickly. Conversely, executing too slowly will extend the restructuring timeline and expose assets to the increased risk of implementation shortfall. Either scenario can have material impact on the cost and quality of the restructuring. It is a transition manager's job to evaluate each portfolio constituent and the expected risk/cost tradeoff in order to design and implement a suitable restructuring strategy, while satisfying the client's timing objectives.

Implementation Issues Specific to Fixed Income

The optimal fixed income transition strategy addresses various concerns:

- Sector misweights
- Term-structure profile differences
- Illiquid securities

9. This may reflect a variety of factors. For example, clients may choose to wait for month-end to allow for greater crossing opportunities; for international transitions, there may be delays in asset delivery.

- Foreign currency
- Timing preferences

Although many of these are common portfolio characteristics, it is crucial to implement a strategy that will decrease the costs associated with portfolio-specific nuances across these parameters. Another of the transition manager's responsibilities is to dissect structural differences between the target and legacy portfolios and then create an optimized transition strategy that will mitigate risks born of those structural differences.

Evaluating Liquidity Sources

Managers must evaluate the many details of each fixed income security to identify the correct liquidity source. Common descriptive data points such as coupon type, maturity, subordinate structure, and issuer are reviewed and logged. There may be numerous issues with various structures, and each issuance may be brought to market by different banking syndicates. For example, there are nearly 30 different corporate bonds listed for IBM, with various terms to maturity and coupon types, as opposed to just one equity security. And this is only for one type of fixed income security. Legacy portfolios may hold many different types of securities (mortgage-backed securities, Treasuries, corporates, munis, etc.). The diverse array of security types makes it increasingly complex to identify the correct liquidity sources for each asset during a restructuring. To effectively evaluate liquidity sources, a trading desk must have expertise across the various markets and security types. Trade research teams can also help identify trading bottlenecks, optimal execution dates and preferred trading counterparties.

Using Derivatives to Manage Risk or Lower Cost

Derivatives can play an important role in fixed income transition management, particularly when liquidity is hindered and formidable differences exist between the legacy and target portfolios' risk characteristics. Since decreasing the performance difference between a legacy and target portfolio is paramount when minimizing implementation shortfall, the ability to quickly and inexpensively restructure the risk characteristics of a portfolio is key.

Derivatives are commonly used during transitions to alter the legacy portfolio's duration. They are an especially important tool when the liquidity timeline of the legacy portfolio is expected to be slow. U.S. Treasury futures contracts have proved particularly useful during transitions: They can be entered into quickly, in large notional sizes, with little or no market impact, and with minimal funding. Derivatives are also used to address sector misweights during a restructuring.

In situations in which operational and legal hurdles make derivatives less efficient, exchange-traded funds (ETFs) may be a more effective option, particularly when beta exposure is desired prior to selecting the target manager. Investors can achieve a diversified sector exposure using ETFs without increasing idiosyncratic risk, which can be associated with large volumes of cash securities.

CASE STUDY OF RISK MANAGEMENT

Having established the framework for transition management, we turn to a case study that illustrates some of the risk factors described above and the role that derivatives can play to reduce risk during a transition. An investment committee decided to shift the duration of a $100 million U.S. Treasury portfolio in its defined benefit plan, moving from exposure at the middle of the maturity curve to a concentration at the short and long ends of the curve. The legacy portfolio is benchmarked to a 7–10 year index; the target portfolio has more of a barbell shape, roughly 60% at the 1–3 year range and 40% at the 20+ year range. Despite the very different compositions, both portfolios have the same weighted-average duration (7.26 years).

There is, however, a mismatch in key rate duration between the two portfolios, or how sensitive each component is to changes in interest rates (Exhibit 54–2). This mismatch could translate into significant risk, even over the course of just one trading day. Consider the impact an abrupt increase in rates at the 15-year point could have had on this portfolio during a transition (Exhibit 54–3).

Price changes range from $0.51 (or 4 bps of yield) on the 15-year bond to $1.10 (or 7 bps of yield) on the 30-year bond. Given the asymmetric nature of bond prices, it is typical to see higher price dispersion at the long end of the yield-curve. Analyzing the portfolio in terms of its key rate duration helps identify where risk resides on the maturity curve.

In this interest rate shock environment, the difference between the two portfolios' term structure profiles created a tracking error valued at $310,000. Approximately 10% of the expected annualized yield was at risk for this single restructuring.

EXHIBIT 54–2

Key Rate Durations

EXHIBIT 54–3

Impact of Interest-Rate Shock on 1/13/11

Sources: BlackRock and Barclays Capital, as of 1/13/11.

The strategy for this transition focused on managing the portfolio's key rate risk. The night before the 7–10 year holdings began to trade, futures contracts were bought and sold to rebalance the legacy portfolio's key rate duration profile and better match the profile of the target portfolio. All five contracts were either bought or sold, decreasing exposure at the belly of the curve and increasing exposure at the long end. This single transition almost completely mitigated the mismatch in expected return between the portfolios; annualized active risk shrank from 491 to 24 bps.

As the 7–10 year trades were completed, the futures contracts were unwound and proceeds were used to purchase the target constituents.

Had the transition strategy focused on weighted-average duration—instead of key rate duration—the long bond risk would have been masked and the portfolio would have been vulnerable to price changes from the steepening rate curve.

Even though both the legacy and target portfolios held only U.S Treasuries (which carry neither credit-spread nor idiosyncratic risk) significant value was at risk in this portfolio restructuring. Fixed income transitions typically involve more than just a shift in Treasury duration, which means a heightened need for analytics and process that protect portfolio value throughout each restructuring.

KEY POINTS

- Transition management is the process of restructuring a portfolio in a way that optimizes the risk/cost tradeoff.
- Fixed income transitions are often complicated and potentially costly. The fixed income market structure offers less transparency and is more demanding in terms of identifying and evaluating liquidity; the diverse types of instruments presents additional trading challenges and varied risk factors (compared with equities).

- Because normal market volatility can put a large amount of the expected annualized return of a fixed income portfolio at risk during a transition, the ability to systematically manage the transition is imperative.
- Two metrics in particular can help investors evaluate their restructuring. Tracking error measures the level of active risk for the portfolio. Implementation shortfall gauges how a portfolio performed during the restructuring period.
- Derivatives are an important tool for managing risk and cost for fixed income transitions. They can be entered into quickly, in large notional sizes, with little or no market impact, and with minimal funding.

CHAPTER
FIFTY-FIVE

MANAGING THE SPREAD RISK OF CREDIT PORTFOLIOS USING THE DURATION TIMES SPREAD MEASURE

ARIK BEN DOR, PH.D.
Director, Barclays Capital

LEV DYNKIN, PH.D.
Managing Director, Barclays Capital

JAY HYMAN, PH.D.
Managing Director, Barclays Capital

The standard presentation of the asset allocation in a portfolio or a benchmark is in terms of percentage of market value. It is widely recognized that this is not sufficient for fixed income portfolios, where differences in duration can cause two portfolios with the same allocation of market weights to have extremely different exposures to macro-level risks. As a result, fixed income portfolio managers have become accustomed to expressing their allocations in terms of contributions to duration—the product of the percentage of portfolio market value represented by a given market cell and the average duration of securities comprising that cell. This represents the sensitivity of the portfolio to a parallel shift in yields across all securities within this market cell. For credit portfolios, the corresponding measure would be contributions to spread duration, measuring the sensitivity to a parallel shift in spreads. Determining the set of active spread duration bets (the differences between the exposures of the portfolio and the benchmark) from various market cells and/or issuers is one of the primary decisions taken by credit portfolio managers.

Yet all spread durations were not created equal. Just as one could create a portfolio that matches the benchmark exactly by market weights, but clearly takes more credit risk (e.g., by investing in the longest duration credits within each cell), one could match the benchmark exactly by spread duration contributions and still take more credit risk—by choosing the credits with the widest spreads within each cell. These credits presumably trade wider than their peer groups for a reason; that is, the market consensus has determined that they are more risky—and are often

referred to as "high-beta" credits, because their spreads tend to react more strongly than the rest of the market to any systematic shock.

Based on this idea, and following an extensive analysis of corporate bonds' spread behavior, we have advocated since 2005 a new measure of risk sensitivity that utilizes spreads as a fundamental part of the credit portfolio management process. To reflect the view that higher spread credits represent greater exposures to sector-specific risks, we represent sector exposures by contributions to duration times spread (DTS), computed as the product of market weight, spread duration, and spread. The shift from spread duration exposures to DTS exposures as the measure of market risk embraces a different paradigm for credit-spread movement—in the form of relative spread changes rather than parallel shifts in spread.

The paradigm shift resulting from the DTS concept has many implications for portfolio managers, both in terms of the way they manage exposures to industry and quality factors (systematic risk) and in terms of their approach to issuer exposures (non-systematic risk). First, modeling spread changes in relative rather than absolute terms generates improved forward-looking estimates of excess return volatility. Second, for computing the hedge ratios needed to form market-neutral credit trades, DTS is superior to "empirical betas" as a measure of market sensitivity. Third, for index replication, matching sector-quality allocations of a credit index in terms of contributions to DTS leads to improved tracking compared with matching the contributions to spread duration. This same way of viewing macro exposures can help to more accurately express active portfolio weights as well. Fourth, DTS-based issuer limits can be considered as an alternative to more standard caps on issuer market weight when imposing portfolio diversification constraints. Finally, the incorporation of the DTS approach into the design of multifactor risk models can help make such models more robust, more compact, and more accurate. In this chapter, we will explore each of these applications in turn, after a brief overview of the large body of evidence supporting the DTS concept.

THE NEED FOR A NEW MEASURE OF CREDIT SPREAD EXPOSURE

Two examples of market conditions when spread duration contributions do not suffice are shown in Exhibit 55–1. During the dot.com crisis, a relief rally in January 2001 led to a temporary tightening of spreads throughout the communications sector. However, that rally was not characterized by a purely parallel shift; rather, issuers with wider spreads tightened by more. Panel A displays the changes in spreads experienced in that month by the key issuers that made up the communications sector of the Barclays Capital Corporate Index.[1] Panel B shows

1. "Key issuers" refers to issuers that had outstanding issues with market value in excess of 1% of the sector aggregate market value. Panel A shows 17 issuers that represented 216 outstanding issues; Panel B includes 19 issuers and 420 bonds.

EXHIBIT 55–1

Spread Changes of Key Issuers in the Communications and Banking Sectors of the Barclays Capital U.S. Corporate Index

Panel B. Banking Sector, December 2010.

Source: Barclays Capital.

the spread tightening in the key issuers in the banking sector during the month of December 2010; a similar effect is seen in this industry-wide rally.

Motivated by market events of this type, we conducted an extensive analysis of corporate bonds' spread behavior and developed a new measure of spread risk sensitivity. As higher spread credits have greater exposures to sector-specific risks, we represent sector exposures by contributions to duration times spread (DTS), computed as the product of market weight, spread duration, and spread. An overweight of 5% to a market cell implemented by purchasing bonds with a spread of 80 bp and spread duration of three years will be considered to be equivalent to an overweight of 3% using bonds with an average spread of 50 bp and spread duration of eight years ($0.05 \times 0.80 \times 3 = 0.03 \times 0.50 \times 8 = 0.12$).

How does this make sense? As mentioned, a portfolio's contribution to spread duration within a given market cell is its sensitivity to a parallel shift in spreads across all bonds in that cell. What is the intuition behind this new measure?

In fact, the intuition is very simple. Let us look at a simple expression for the return of a given bond due strictly to change in spread R_{spread}. Let D denote the spread duration of the bond and s its spread; the spread change return is then given by

$$R_{spread} = -D \cdot \Delta s \tag{55–1}$$

It is quite easy to see that this equation is equivalent to

$$R_{spread} = -(D \cdot s) \cdot \frac{\Delta s}{s} \tag{55–2}$$

That is, just as spread duration is the sensitivity to an absolute change in spread (e.g., spreads widen by 5 bp), DTS is the sensitivity to a relative change in spread (e.g., spreads increase by 5% of their current levels). Note that this notion of relative spread change provides for a formal expression of the rough idea discussed above—that credits with wider spreads are riskier since they tend to experience greater spread changes in absolute terms.

Based on the absolute spread change approach in Eq. (55–1), the volatility of excess returns can be approximated by

$$\sigma_{return} \cong D \cdot \sigma_{spread}^{absolute} \tag{55–3}$$

while in the relative spread change approach of Eq. (55–2), excess return volatility follows

$$\sigma_{return} \cong D \cdot s \cdot \sigma_{spread}^{relative} \tag{55–4}$$

Given that the two representations above are equivalent, why should one of them be preferable to another? The key advantage of the DTS approach of Eq. (55–4) is that relative spread volatilities are much more stable than absolute spread volatilities. We found extensive empirical evidence that the volatility of absolute spread changes of U.S. corporate bonds (both systematic and idiosyncratic) is linearly proportional to spread level, irrespective of sector, maturity, credit quality or time period.[2] This implies that the second approach, based on relative spread changes, should generate more accurate projections of spread volatility.

EXHIBIT 55–2

Time Series Volatility of Systematic Spread Changes vs. Spread Level

Based on monthly observations for all constituents of the Barclays Capital Corporate and High-Yield Indices rated B or better, September 1989–January 2005.
Source: Barclays Capital.

SPREAD VOLATILITY AND DTS

The relation between the volatility of systematic spread changes and the average beginning-of-month spread level is plotted in Exhibit 55–2. The analysis was carried out using a large sample with more than 560,000 monthly observations on all constituents of the Barclays Capital Corporate and High-Yield Indices rated B or higher between September 1989 and January 2005.[3] Bonds in each of the three main sectors (financials, industrials, and utilities) were divided into three equally populated duration buckets (short, medium, and long). Bonds in each duration bucket were then partitioned into prespecified cells based on spread. Spread cell breakpoints varied across sector and duration to ensure that each spread cell was well populated monthly.[4] This procedure resulted in 66 distinct time series data sets; each consisted of a fairly homogeneous set of bonds with monthly data for

3. See Ben Dor, Dynkin, Houweling, Hyman, van Leeuwen, and Penninga, "DTS (Duration Times Spread): A New Measure of Spread Exposure in Credit Portfolios" for further detail regarding the analyses shown in Exhibits 55–2 and 55–3. In this section, we report our original results using data through 2005. In what follows, we use market data after this date as an extreme out-of-sample test of these relationships.

4. Bonds were assigned to one of 66 cells with breakpoints ranging from 100 bp to more than 500 bp (the financial, industrial and utility sectors had seven, nine, and six spread cells for each maturity bucket, respectively). To eliminate idiosyncratic effects, months in which a cell was populated by fewer than 20 bonds were excluded. Employing a weighted volatility estimate instead (in which the number of observations in each month was used as the weighing factor) produced very similar results.

their spreads and spread changes. The systematic spread change in a given cell each month was represented simply as the average spread change across all bonds that comprised that cell. We then calculated the time series volatility of these systematic spread changes and the average spread over time for each cell.

The results indicate an almost perfect linear relationship between spread volatility and the level of spread that can formally be expressed as:

$$\sigma_{spread}^{absolute}(s) \cong \theta \cdot s \tag{55–5}$$

Estimating a simple regression based on Eq. (55–5) provides an excellent fit to the data (R^2 in excess of 90%) with the slope coefficient θ equal to 9.1% using all observations and 9.4% if the three circled outliers are excluded.[5] Furthermore, for a given level of spread, the differences across sectors and maturity buckets are fairly small. Hence, the historical volatility of systematic spread movements can be expressed quite compactly, with only minor dependence on sector or maturity, in terms of a relative spread change volatility of about 9% to 10% per month. That is, spread volatility for a market segment trading at 50 bp should be about 4.5–5.0 bp/month, whereas that of a market segment at 200 bp should be about 18–20 bp/month.

We also studied whether idiosyncratic spread volatility is similarly related to the level of spreads. We computed the standard deviation of the differences between all individual bonds' spread changes and the average spread change of their respective cell, pooled across all bonds and months. This pooled measure of idiosyncratic spread volatility per market cell was then plotted against the median spread of the cell. We again found a very strong linear relationship between spread and idiosyncratic spread volatility, with a slope similar to that estimated for systematic volatility.

To corroborate these findings, we also investigated the relation between excess return volatility and DTS. If the volatility of systematic spread changes is proportional to the level of spread, then Eq. (55–4) implies that a portfolio's excess return volatility should increase linearly with its DTS, with the slope equal to the volatility of relative spread changes. In addition, excess return volatility for portfolios with similar DTS should be approximately equal even if their spreads or spread durations differ.

To examine these predictions, bonds were assigned into DTS quintiles, which in turn were further subdivided into six equally populated buckets based on spread. The average excess returns and median DTS were calculated monthly for each bucket separately. These statistics were then used to compute the excess return volatility and average DTS for all time-series.

5. The population of the three highest spread cells (bonds trading at spreads above 500 bps) was very scarce for most of the study period. Consequently, most of their monthly spread realizations were excluded (due to the minimum bond population requirement). The statistical relevance of these most extreme data points is therefore questionable.

EXHIBIT 55–3

Excess Return Volatility vs. DTS

Based on monthly observations for all constituents of the Barclays Capital Corporate Index, September 1989–January 2005.
Source: Barclays Capital.

The results of this analysis are presented in Exhibit 55–3, which plots the time series volatility of excess returns for each of the quintile-bucket combinations against its average DTS. First, it is clear that excess return volatility increases with the level of DTS and that a straight line through the origin provides an excellent fit. This is indeed confirmed by a regression of the excess return volatility against the average DTS, which finds a fit of 98% and an insignificant intercept. Furthermore, the estimate of the slope coefficient (8.8%) is in line with the volatility of relative spread changes found in Exhibit 55–2 as expected. Second, observations representing the same DTS quintile exhibit very similar excess return volatilities despite large difference in their spreads and durations.[6]

In 2009, we re-examined whether the key findings underlying the DTS concept remained valid through the credit crisis of 2007–2009.[7] We showed that the fundamental relationship between the level of spread and subsequent volatility persisted in a linear fashion across all sectors and credit ratings, although the proportionality factor increased from 10% to about 15%. While this implies that a long-term calibrated DTS model would not have fully captured

6. The one exception to this is in the highest DTS quintile, where the subdivision by spread causes wide variations in DTS as well. As a result, the observations no longer form a tight cluster, but they continue to follow the same general relationship between DTS and excess return volatility.
7. Madhur Ambastha and Arik Ben Dor, "DTS (Duration Times Spread) in the Credit Crunch: Did It Live Up to Expectations?" *Barclays Capital* (April 2009).

spread risk during the crisis months, we demonstrated that it was far more effective than any other spread duration–based measure. The explicit use of spread in the DTS framework as a barometer of risk proved to be of paramount importance in managing credit portfolios during that volatile period.

The concept of spread proportionality and DTS are not limited only to U.S. corporate bonds. From a theoretical standpoint, we showed that structural credit risk models such as the Merton model imply a near-linear relationship between spread level and volatility.[8] Subsequent empirical studies indeed found that the applicability of DTS extends to other spread asset classes with a significant default risk. For example, we investigated the dynamics of CDS spreads[9] in both the U.S. dollar and euro markets using a different estimation approach, sample period and data frequency than those used in the original study of U.S. corporate bonds. Despite these differences in data and technique, we found clear evidence of a linear relation between spread volatility and spread level with a very similar slope.[10] Similar results were documented for European corporate and sovereign bonds and emerging market sovereign debt denominated in U.S. dollars.[11]

RISK PROJECTION: PREDICTING SPREAD VOLATILITY

Perhaps the most important requirement for managing a credit portfolio successfully is the ability to measure its risk accurately. A key benefit of DTS in the context of generating volatility forecasts is its use of current spread levels to quickly adapt to changing market conditions. In contrast, estimates based on past realized spread volatility can take longer to adapt, depending on the time window used for calibration. The selected time period is inherently subjective, and may not perfectly reflect the current state of the market.

The credit crisis of 2007–2009 provides an excellent opportunity to examine the differences between forecasts based on DTS and traditional measures relying on historical realized spread changes for at least two reasons. First, the magnitude

10. Ben Dor, Polbennikov, and Rosten (2007) used maximum likelihood to estimate the relation between spread volatility and spread level of individual U.S. and European default swaps, based on weekly data over the period July 2004 and May 2006.
11. See Arik Ben Dor, Lev Dynkin and Jay Hyman, "DTS—Further Insights and Applicability," *Lehman Brothers* (August 2005). Arik Ben Dor, Albert Desclée, Jay Hyman and Simon Polbennikov, "Managing European Sovereign Spread Risk," *Barclays Capital* (August 2010). Madhur Ambastha, Arik Ben Dor and Lev Dynkin, "DTS (Duration Times Spread) for Emerging Market Securities—A New Measure of Spread Exposure," *Lehman Brothers* (February 2007).

of the crisis was unprecedented. Spreads of U.S. investment-grade bonds widened to an all-time high of more than 6%, from lows of around 1% in the benign 2003–2006 period. Similarly, spreads of high-yield bonds rose to more than 18% and credit default index swap (CDX) spreads increased by a factor of five. Not only the magnitude, but also the extraordinary speed at which spreads widened, caught many investors off guard, with risk estimates calibrated to the sustained "volatility drought" of the previous few years severely underestimating the spread risk of corporate bonds. Second, since the concept of DTS was first introduced in 2005, the crisis period presented a true out-of-sample test of its effectiveness.

Exhibit 55–4 shows the monthly spread changes of the Barclays Capital U.S. Corporate Index normalized by several projections of spread volatility from January 2006, well before the first signs of the crisis were observed, through March 2010, when markets were already in recovery mode. The first forecast of volatility, based on DTS, is the product of the spread level at the beginning of the month and the (approximate) relative spread volatility (10%/month) estimated in our original study, based on the analysis shown in Exhibit 55–2. The plot also includes two estimates using the realized volatility over a trailing 36-month window or during the entire history (since September 1989) available as of the start of each month.

The exhibit illustrates that the forecast based on the trailing 36 months would have fit the low volatility level during the pre-crisis period quite well, but was susceptible to large sudden shocks such as in July 2007 and November 2007, which resulted in 5.1 and 6.3 standard deviation realizations, respectively.

EXHIBIT 55–4

Comparison of Volatility Forecasts Based on DTS and Historical Absolute Spread Changes

Normalized spread changes are monthly changes in spreads divided by a forecast of volatility based on DTS with a 10% slope, absolute spread volatility computed over the trailing 36 months or the entire available history since September 1989. The results are reported monthly between January 2006 and March 2010.
Source: Barclays Capital.

Although the estimator gradually adjusted to the change in market conditions, it continued to understate the level of risk more than a year after the crisis began, with an 8.4 standard deviation realization in September 2008.

In contrast, the "long-term" forecast was better prepared at the beginning of the crisis since it incorporated information from previous extreme market events such as the 1998 and 2002 crisis periods. While its forecast of volatility for July 2007, for example, was higher than that of the "short-term" estimator, it generated grossly underestimated risk projections toward the end of 2008. Because adjustment to changing market conditions is slow, the spread change in September 2008 would have corresponded to an 11.6 standard deviation event, using the forecast generated by the long-term volatility measure. Similarly, the estimator underestimated the magnitude of the spread tightening beginning in early 2009 as market conditions started to improve.

The DTS volatility estimates over the period were consistently superior to both forecasts using realized volatilities. The DTS-based forecasts quickly (albeit not perfectly) reflected both the increased level of risk since the crisis erupted and the reversal in market conditions in 2009, with most spread change realizations corresponding to less than two standard deviations. A notable exception was September 2008. Despite the already heightened level of spreads, the combined effect of Lehman Brothers' and Washington Mutual's defaults and the bailout of AIG in that month resulted in a 4.5 standard deviation event. However, as discussed, the forecasts using realized absolute spread volatility underestimated the risk by a factor of between two and three times more than the DTS-based forecast.

The credit crisis that began in 2007 affected not only corporate but also sovereign issuers. The deteriorating economic conditions in several of the euro area economies with high deficits and/or debt ratios subsequently raised solvency concerns among many investors. As a result, spreads of countries such as Portugal, Ireland, Italy, Greece, and Spain widened significantly in 2010 relative to German treasuries, to the point where the risk contribution of sovereign spreads in investment-grade bond indices grew larger than that of corporate bonds.[12] Many market participants had to suddenly re-evaluate their risk management practices. It was apparent that past volatilities of absolute spread changes could no longer serve as a basis for forward-looking risk projections in this market, as sovereign spreads had mostly been very tight and stable since the inception of the Euro in 1999. The DTS paradigm, keying on rising spread levels, does not require a long period of increased spread volatility to warrant an increase in forward-looking risk estimates. Furthermore, as mentioned earlier, theory suggests that DTS should apply to all securities with a credit component irrespective of the issuing entity, and earlier results indeed confirmed it is applicable to emerging market countries. Therefore, it is interesting to see to what extent using the DTS paradigm to project the spread risk of Euro sovereign issuers could have helped investors in this asset class.

12. See Ben Dor, Desclée, Hyman, and Polbennikov, "Managing European Sovereign Spread Risk."

Exhibit 55–5 compares the daily spread volatility of several Euro countries over two distinct periods, which roughly span the time period of the crisis. Volatility between August 2008 and July 2009 is represented on the horizontal axis, whereas the vertical axis reflects the volatility in the period from August 2009 to July 2010. The time partition was selected such that both periods have about the same length but correspond to different stages of the sovereign debt crisis. Each observation represents either the absolute or relative spread volatility of a particular country. Observations along the diagonal line indicate that the volatilities are the same over the two time periods.

Two clear patterns can be observed in the plot. First, most of the observations representing absolute spread volatilities are located quite far above the line, pointing to a marked increase in volatility in the second period of the sample. In contrast, relative spread volatilities are quite stable, with almost all observations located near the straight line crossing the origin, which represents equal volatilities (absolute or proportional) in both periods. This is because the pick-up in volatility in the second period was accompanied by a similar increase in spreads. In particular, the daily volatility of absolute spread changes for Greece increased by a factor of almost 10 (from 5.9 to 51.6 bp), whereas in relative terms it only increased from 4.3% to 6.8%.

EXHIBIT 55–5

Absolute and Relative Volatility of Daily Spread Changes for Selected European Sovereign Issuers

Both absolute and relative spread volatilities are expressed in units with similar magnitudes. However, the interpretation is different: an absolute spread change of 10 represents a 10 bp widening in a country spread, while a relative spread change of 10 means that spreads changed by 10% of their current values (e.g., from 50 to 55, from 200 to 220).
Source: Barclays Capital.

Second, the daily volatilities[13] of relative spread changes in various countries are quite tightly clustered, ranging from 4.5% to a bit over 8%, whereas the range of absolute volatilities is much wider, ranging from 1.6 to more than 17 bp for Portugal and even higher for Greece. Furthermore, spread proportionality seems to capture well not only the spread dynamics of the countries that were in the center of the crisis (Portugal, Greece, Spain, Ireland, and Italy), but also countries that were less affected such as Belgium and France. While the exhibit suggests that absolute spread volatility also remained essentially unchanged for these two countries, using relative spreads offers the advantage of similar volatilities across all sovereign issuers.

Exhibits 55–4 and 55–5 provide an illustration of the advantage of the DTS approach compared with the risk estimated based on absolute spread changes. The DTS approach does not require a subjective selection of an historical calibration period, and allows for a rapid incorporation of market conditions as reflected in the level of spreads. This feature can be especially valuable in situations where market volatilities exceed any historical precedent, as illustrated in these two exhibits for the credit and sovereign crises of 2007–2010. It is also important to note that DTS-based risk forecasts can immediately adapt to changing conditions. Whereas models based on realized monthly volatility will only be updated at the end of a month, DTS estimates can be updated as soon as spread changes are marked—intra-month or even intra-day.

HEDGING: PREDICTING SENSITIVITIES TO MARKET SPREAD CHANGES

Another natural application of DTS is hedging. Consider an investor whose basic goal is to express a view favoring one issuer over another while taking as little directional market risk as possible. The primary driver of the performance of such a strategy should be the investor's skill at forming views on issuers, while any systematic risk is to be minimized. The success or failure in isolating

13. The results in this section are based on daily data due to the fairly short time period of relevance. The relative spread volatilities reported here thus seem to be much higher than those reported earlier for credit markets. Assuming that all daily spread changes are independent, and that a month contains about 20 business days, a 6% daily volatility would correspond to a monthly relative spread change volatility that is greater by a factor of $\sqrt{20}$, or more than 26%. This apparent discrepancy reflects in part the fact that the analysis in this section directly examines the spread volatilities of individual issuers, without any attempt to separate systematic from issuer-specific effects. If we compute the total spread volatility for an issuer using our estimates of systematic and idiosyncratic spread volatility updated through the 2007–2008 credit crisis (15% per month), the implied *total* spread volatility of about 21% per month is not so different from the daily results (converted to a monthly frequency) shown here for euro sovereigns. It also underscores the approximate nature of this square root rule and the difficulty of comparing daily and monthly volatilities.

issuer-specific risk lies in his ability to forecast the market beta of each security over the return horizon.

Say we are considering a trade as of December 31, and plan to hold it in position for three months. The betas we would like to use for this hedge are the as-yet unknown ones that we will find *ex post* as we later review the returns realized from January through March. What is the best forecast we can make given the data we have at our disposal? An obvious approach would be to use DTS. Since the DTS contribution of a position measures its systematic spread exposure, DTS neutrality should be the best way to hedge the market exposure of an issuer-specific trade that goes long one issuer and short another.

To examine this question, we conducted a study that compared two different methods for forecasting the market betas of individual CDS over a given period using only data available at the beginning of the period.[14] The first relied on the ratio of the DTS (in this case, risky PV01 times spread) of the individual CDS to that of the market as of the beginning of the period. The second approach was one commonly used by investors, based on the empirical beta of the individual CDS to the market from the prior period. We divided the dataset, which contained roughly three years of weekly data, into nonoverlapping periods of equal length, either 26 weeks or 52 weeks each. For each period but the first, the beta of each security was estimated using the two methods: either by using the spread as of the start of the period, or by using the security's beta from the prior period. We then regressed the realized beta during the period on each of these two candidate predictors. Since there were 84 issuers in each period, the regressions had 5×84 observations when a 26-week estimation period was used and 2×84 observations when a 52-week estimation period was used. The results of these regressions are shown in Exhibit 55–6.

Several things are apparent from Exhibit 55–6. First, we see that the DTS ratio provides a better prediction of next-period beta, with R-squared values approximately twice as high as those using the prior-period empirical betas. Second, the regression results tell a very different story for the two models. When using the DTS ratio, the intercept is not statistically significant, and the coefficient is very close to one; that is, the DTS ratio as of the start of the period is an unbiased estimate of market beta in the coming period. For the empirical betas, this is not the case. The intercept plays nearly an equal role as the prior period beta, both in terms of the coefficients and the t-statistics. This means that if we want to forecast the next-period beta based on the empirical beta observed in the prior period, an unbiased forecast would be to assume that the beta will be halfway between the prior observation and 1. That is, betas are mean-reverting. This observation dovetails nicely with the established literature on empirical betas in equity markets. For example, Grinold and Kahn make the following observations regarding equity betas:

> A stock with a high historical beta in one period will most likely have a lower (but still higher than 1.0) beta in the subsequent period. Similarly, a stock with a low beta

EXHIBIT 55–6

Predictors of Market Beta Based on Start-of-Period DTS Ratios or Prior-Period Empirical Betas

Explanatory Variable for Predicting Beta	Time Period for Beta Estimation	R - Squared	Variable	Regression Results	
				Coefficients	t Stat
Prior-Period Empirical Beta	26 weeks	0.19	Intercept	0.56	9.83
			Prior-Period Beta	0.44	9.85
Prior-Period Empirical Beta	52 weeks	0.23	Intercept	0.49	5.63
			Prior-Period Beta	0.51	6.97
DTS Ratio	26 weeks	0.36	Intercept	–0.09	–1.1
			DTS Ratio	1.09	15.31
DTS Ratio	52 weeks	0.5	Intercept	–0.04	–0.5
			DTS Ratio	1.05	12.86

Source: Barclays Capital.

in one period will most likely have a higher (but less than 1.0) beta in the following period. In addition, forecasts of betas based on the fundamental attributes of the company, rather than its returns over the past, say, 60 months, turn out to be much better forecasts of future betas.[15]

Rosenberg provides empirical evidence supporting this statement and shows how the predicted betas from Barra's E1 risk model do a much better job of forecasting next-period betas than just using historical betas.[16] His results indicate that a simple regression of the beta in one period on the historical beta from the prior period yield a coefficient of 0.58.

These results can perhaps help add another perspective to the DTS concept in general. Upon their first exposure to the DTS approach, some investors have noticed a striking similarity to the more familiar concept of beta-adjusted spread durations. Both of these approaches recognize that a systematic change in spreads throughout an industry does not tend to result in a parallel shift, but that some issuers will move by more than others. The difference between the two methods is that in one approach, the forward-looking market beta is estimated based on its past market beta, while in the other it is estimated based on its current spread level. Based on the head-on comparison of the two estimation methods shown in

15. Richard C. Grinold and Ronald N. Kahn, *Active Portfolio Management*, 2nd ed. (New York: McGraw-Hill, 2000), p. 14.
16. Barr Rosenberg, "Prediction of Common Stock Betas," *Journal of Portfolio Management* (Winter 1985), pp. 5–14.

Exhibit 55–6, we can bring the two approaches into agreement. A portfolio's DTS exposure to a sector can now be seen to be equivalent to its beta-adjusted spread duration exposure, with the estimation of the betas provided by the market in the form of spreads.

After exploring the use of DTS to estimate hedge ratios of individual issuers relative to the market, we applied this approach to hedging paired long/short trades in CDS of two issuers from the same industry.[17] Selecting a pair of issuers x and y from a given industry at random, we would go long one unit of x (by selling protection) and hedge the systematic sector exposure by going short some amount of issuer y (by buying protection). A hedging strategy that used DTS ratios to determine the amount of issuer y to use was compared with one based on empirical betas. The details of this analysis are somewhat involved, and beyond the scope of this chapter, but they once again established the superiority of DTS-based hedge ratios over those based on empirical betas. The DTS-hedged trades were found to have lower P&L volatilities, more stable hedge ratios, and a smaller percentage of variance from systematic changes in sector spreads. Empirical betas proved to be more difficult to estimate, and prone to instability.

The DTS approach to hedge formation has several clear advantages. First, the calculation of the hedge ratio is simple and unambiguous and spares the investor some difficult decisions about how beta should be estimated (what frequency data? how long a window? Should recent data count more than older data?). Second, the DTS ratio has shown itself to be both a good predictor of market beta at the individual issuer level and a reliable mechanism for neutralizing the market exposure of long/short trades. Finally, when dealing with long/short trades in swaps of matched maturities, the DTS-neutral trade will be carry-neutral as well,[18] neatly avoiding the possibility of forming a portfolio with negative carry.

Although we restricted our investigation to the hedging of individual issuers and paired long/short trades in CDS, the results are applicable to a much broader portfolio context. Even portfolio managers who are able to take long/short positions in CDS do not necessarily hedge each trade on its own. Rather, long and short positions are established according to the manager's views, and the aggregate exposures of the portfolio are hedged to achieve the desired systematic exposures, either passive to the index or to actively reflect the manager's macro views. We believe that the right way to manage spread risk, consistent with the hedging mechanism used here, is to measure industry exposures in terms of net DTS contributions. To maintain a neutral exposure, one would attempt to zero out the exposures in each industry. If a portfolio incorporates active industry

17. For details, see Ben Dor, Hyman, Polbennikov, and Rosten, "Hedging Pairwise CDS Trades Using DTS."

18. If the duration is the same on both sides of the trade, then matching duration × notional × spread will be the same as matching notional × spread, which is exactly the way the monthly premium payments on the CDS are calculated. This means that the monthly premium flows on the two legs of the trade will exactly cancel each other out, and the total return of the trade will be entirely based on spread change.

exposures, the calculation of the overall risk should include correlations among relative spread movements in each sector. This approach is illustrated in the last section, which discusses how a risk model for spread asset classes can be constructed around the notion of DTS.

REPLICATION: CREATING INDEX TRACKING PORTFOLIOS

Portfolio managers often need to build portfolios that closely track the returns of the selected benchmark. Constructing a portfolio of cash instruments to replicate a target index can be accomplished using various methods, but the most commonly used approach is based on stratified sampling. It relies on partitioning the index into cells, which represent the manager's view of common risk factors affecting a given market (e.g., for credit, these might be sector and rating). Bonds are then selected from each "cell" based on certain criteria and weighted such that they match various characteristics of the cell, for example contribution to spread duration. The advantage of this approach is its simplicity and flexibility; its disadvantage is that it ignores the correlations among cells.[19]

In this section, we provide an illustration of the stratified sampling method using the Barclays Capital U.S. Corporate Index, and matching only a single characteristic at a time: DTS or spread duration. Our intention is not to design the "optimal" replicating portfolio, but rather to focus on the relative efficacy of one characteristic relative to the other.

To construct the two replicating portfolios, we first partition the index into 24 cells (eight sectors × three credit ratings).[20] We then select 10 bonds to represent each cell in the portfolio.[21] This same set of 10 bonds is used in both variants of the replicating portfolio, to reduce noise from issuer selection and focus attention on the differences in systematic risk exposures. The key difference is in how we weight the bonds within each cell: in the DTS-based portfolio, we match the DTS exposure of the index in each cell, while in the spread-duration-based portfolio we match the index spread duration exposure.[22] For example, Exhibit 55–7 shows a

19. A stratified sampling approach is "blind" to the relationships among cells. This can be remedied by complementing a stratified sampling approach with the use of an optimizer that accounts for the correlations among cells.
20. The sector breakdown is: Banking, Finance, Basic Industry, Consumer Cyclical, Consumer Non-Cyclical, Communications, Energy, and Utility.
21. The number of bonds selected from each cell is set to 10 since it strikes a good balance between having a realistic size for the replicating portfolio (240 bonds) and reducing idiosyncratic risk. If fewer bonds are used to represent each cell, the variation in tracking errors may reflect not only the difference between the two systematic risk measures (DTS and spread duration), but also the idiosyncratic performance of the set of bonds selected.
22. The scheme used to weight the 10 bonds within each cell is fairly complex, involving a further subdivision of each cell into four quadrants, to ensure that we can match both market weight and the desired additional characteristic by a rule-based algorithm that always results in positive weights to all selected bonds. Details may be found in Ambastha and Ben Dor, "DTS (Duration Times Spread) in the Credit Crunch: Did It Live Up to Expectations?"

market structure report of the Barclays Capital U.S. Corporate Index along the sector/quality partition used for this replication exercise. For each cell of the partition, the report characterizes the exposure of the index to that market segment in three different ways: by market weight, contribution to option-adjusted spread duration (OASD), and contribution to DTS. The spread-duration–based replicating portfolio is constructed such that it matches the contributions to OASD in each of the index sectors (the second column from the right); the DTS-based replication matches the DTS contributions in the rightmost column.

A key part of any index replication attempt is selecting the bonds that form the replicating portfolio. In a real-life portfolio management setting, security selection plays an important role in determining performance and several different criteria can be employed in the security selection process, depending on the portfolio setting. If minimizing tracking error is the primary goal, then the security weights within each cell should focus on the primary issuer exposures of the benchmark. Additionally, managers may aim to maximize liquidity, or to add value by choosing securities that they believe will outperform. Ideally, though, as long as the portfolio has matched the benchmark allocations on the macro level, it should track well in the event of any major industry rally or decline. The key is to match the right set of macro exposures.

For the purposes of this study, our interest is not in the issuer selection mechanism, but in checking which set of macro exposures is most important to match. The selection mechanism therefore does not need to be optimal in any sense (e.g., minimizing tracking error volatility or maximizing performance). Rather, we would like to test our replication methods using several different issuer selection mechanisms, to ensure that differences between the two replicating portfolios (DTS-matched and spread duration matched) are independent of the specific bonds that were selected. One approach is simulation, in which bonds

in each cell would be randomly selected, the replication results recorded, and the analysis repeated multiple times. Another approach, which we use instead, is to specify explicit selection criteria based on bond characteristics. While this approach leads to a single replicating portfolio (per criterion), it more closely mimics a realistic process of constructing replicating portfolios for index tracking purposes.

We analyze five potential bond selection criteria. The first criterion, based on market value, selects 10 of the largest bonds in each cell. Hence, it results in the most investible and liquid portfolios (as larger size is generally associated with increased liquidity). The remaining four criteria are designed primarily to maximize our ability to distinguish between the two replication strategies. The second and third criteria rely on spread and select the bonds with the highest (lowest) level of spread. This represents a replication strategy that tries to maximize carry (minimize risk). The last two criteria use an algorithm designed to maximize the dispersion in either spread duration or DTS among the bonds selected within each cell. Selecting bonds with the maximum potential dispersion in the characteristics used to match the index should magnify the mismatch between the portfolio and the benchmark in terms of the exposures not being forced to match. This in turn would facilitate the comparison between the replication results of the two sensitivity measures.

Exhibit 55–8 presents the tracking error volatilities (TEV) of the replicating portfolios during the 24-month period beginning in January 2007, for the various bond selection criteria. Irrespective of the selection criteria, matching each cell's DTS achieves lower tracking error volatility than matching its spread duration, although the improvement varies widely, from 1.2 bp/month to almost 15 bp/month. Looking at the difference in weight given to each bond under the two matching schemes (reported in the third column) suggests that the reduction in TEV is generally more meaningful as the weight differential increases (i.e., as the replicating portfolios are less similar to each other).[23]

For example, if the selection criterion is market value, the average (absolute) difference in the weight of each selected bond under the two replication schemes (in proportion to the total index market value) is 0.46%, and the TEV declines from 22.9 bp/month for matching spread-duration exposures to 21.4 bp/month when matching DTS exposures. If the maximum-spread criterion is used instead, the weight differential rises to 0.72%, and the decline in TEV when matching DTS rather than spread duration exposures is 14.7 bp/month.

It is important to mention that the superior tracking achieved by matching the index DTS does not come at the expense of performance. The last two columns in Exhibit 55–8 display the average tracking errors of the replicating portfolios.

23. For each selected bond, we calculate the difference in the weight (as a proportion of the index aggregate market value) it is assigned under the DTS and spread duration matching. The weight differential per bond in Exhibit 55–8 is computed as the average of the absolute value of the weight difference for all the bonds selected.

EXHIBIT 55–8

Index Replication Using Stratified Sampling

Selection Criteria	*Tracking Error Vol. (bp/month)*		Weight Differential per Bond (as % of Total Index MV)	*Average Tracking Error (bp/month)*	
	SD Match	DTS Match		SD Match	DTS Match
Market Value (largest)	22.9	21.4	0.46%	–11.5	–8.0
Spread (lowest)	20.7	15.6	0.89%	–10.6	–14.0
Spread (highest)	33.0	18.3	0.72%	–11.7	–4.4
Spread Duration Dispersion	17.0	15.8	0.47%	1.9	5.8
DTS Dispersion	28.2	24.7	0.59%	–6.1	–1.5

Replication of the Barclays U.S. Corporate Index is performed through matching the spread duration (SD) or DTS characteristic of each of the 24 cells in the partition (8 sectors × 3 credit ratings). Based on monthly observations (January 2007–December 2008).
Source: Barclays Capital.

The results indicate that while our simple replication exercise tends to underperform the index for any bond selection criteria, the DTS-based approach gives better average tracking errors (with one exception) than the spread duration-based one.

The use of DTS exposures to replicate an index by stratified sampling is far from a theoretical exercise. This approach has been used to form a highly liquid portfolio of bonds to track the Barclays Capital U.S. Investment-Grade Credit Index.[24] A purely rules-driven sampling methodology ensures transparency. The replication methodology uses a partition of five sectors by five duration categories, with each cell represented by two bonds. The bonds are selected based on a proprietary measure of liquidity, and are weighted such that the index DTS exposure in each cell is matched. Historical backtesting of this strategy indicates that it tracks the index much more closely than an alternative strategy based on liquid derivatives including Treasury futures, swaps, and CDX.

EXPRESSING MACRO VIEWS IN ACTIVE PORTFOLIOS

Attention to the DTS exposures of a portfolio is essential for active portfolio managers as well as passive ones. In many financial institutions, the management of a portfolio is a team effort with distinct tasks for different players. Often, one

24. Ariel Edelstein, Siddhartha Dastidar, and Bruce Phelps, "Tradable Credit Portfolio (TCX) to Track the USD IG Credit Index," *Barclays Capital* (April 2010).

group forms a set of macro views and expresses them as a set of overweights and underweights to various market segments that the portfolio should adopt relative to the benchmark. A second group may be charged with the implementation of this plan in terms of individual securities, often following the issuer selection advice of yet a third group. Yet, in order to achieve the most accurate implementation of the macro views, they must be expressed in terms of the type of exposures that best reflect the way the market moves. Referring back to the index profile shown in Exhibit 55–7, we saw that the passive credit investor will most effectively replicate the macro exposures of the index by matching the DTS contributions in the far right column, not the market value weights or the contributions to OASD. Similarly, the active investor should express the desired overweights and underweights relative to the benchmark in terms of contributions to DTS.

PORTFOLIO CONSTRUCTION: OPTIMAL DIVERSIFICATION OF ISSUER RISK

In the management of all but the most passive credit portfolios, the sizing of credit exposures must find the right balance between two opposing needs. To control risk, it is important to avoid taking a position in any given issuer that is overly concentrated. Conversely, to generate alpha based on analyst recommendations, it is important that the recommended names have sufficient weight in the portfolio to drive outperformance; overemphasis on diversification can dilute the value of issuer selection. As a result, investors often seek guidance on what the "correct" level of diversification should be for a given portfolio.

In the traditional approach to portfolio diversification, a plan sponsor imposes constraints on the portfolio that specify the maximum percentage of the portfolio, by market weight, that may be invested in any single issuer. This issuer limit may be dependent on credit quality, allowing larger concentrations in higher-rated issuers. In the past, we have formulated an approach to optimally determine these quality-dependent limits, based on an empirical study of the performance impact of downgrades.[25] This analysis determined that the ratio of allowed position sizes should be based on the relative risks in different quality groups. If the sole concern is downgrade risk, then the ratio indicated based on credit market data gathered from 1988 through 2001 was approximately 9:4:1. This means that if we take the allowed portfolio weight in a Baa-rated issuer as our unit size, a position in a security rated A may be four times as large and positions in Aa-Aaa issuers may be nine times as large. If "natural" spread volatility, which occurs in the absence of a ratings transition, is included in the risk measure as well, the discrepancy between the different ratings categories is lessened, and the ratio becomes 4:3:1. A recent update of this model found that the experience

25. Lev Dynkin, Jay Hyman, and Vadim Konstantinovsky, "Sufficient Diversification in Credit Portfolios," *Journal of Portfolio Management* (Fall 2002), pp. 61–75.

during the 2007–2009 crisis was not supportive of large concentrations even in higher-rated issuers. The same model, updated to include data through the end of 2010, found that the optimal position size ratios were 2.8 : 1.6 : 1 based purely on downgrade risk and 2.6 : 1.6 : 1 when including the effect of all nonsystematic risk, both from downgrades and natural spread volatility.

How can we apply the DTS model to this problem? A first step to this end would be to retain the framework of ratings-dependent caps on issuer market-weight, but compute the position size ratios based on the ratios of average DTS levels in each credit quality group. This approach gives ratios that change over time as spreads widen and tighten, responding quickly to changing market conditions rather than needing to wait for an *ex post* analysis of realized losses. For example, as of December 2001, the position size ratio from the DTS method was 4.3 : 1.7 : 1, similar to the result from the empirical approach including the risk of both downgrades and natural spread volatility. As market volatility (and spread) ground lower in the following years, these ratios increased, peaking in March 2005 at 6.6 : 3.0 : 1. However, when spreads skyrocketed in 2008, the ratio of position sizes declined, reaching as low as 1.4 : 1.1 : 1 in September 2008, as all credit qualities were deemed highly risky. As of December 2010, the DTS-based ratio of 2.1 : 1.4 : 1 agreed well with that from the updated empirical study.[26]

However, the DTS paradigm shift suggests a completely different approach to controlling portfolio concentrations, not just a simple recalibration. Rather than imposing a limit on the portfolio market weight in a given issuer (with the size possibly dependent on quality), a limit on the DTS contribution of any issuer should be imposed regardless of credit quality. This would have the effect of allowing a portfolio to have large concentrations in low-spread issuers while enforcing stricter diversification constraints on high-spread issuers. While this idea is attractive in principle, its implementation encounters several practical problems, as we shall discuss.

This DTS-based approach is in some ways quite similar to the traditional approach, in which issuer caps are specified in terms of market weights that differ based on credit quality; yet there are some crucial differences. In both schemes, the fundamental principle is to allow greater concentrations to issuers perceived to be less risky, and require more diversification where risk is greater. The fundamental difference between the two methods is the source of the risk assessment: the quality assigned by the ratings agencies or the spread assigned by the market. There are advantages to each.

Market weight limits based on credit ratings are very well suited for specifying the investment policy for a particular mandate. A permitted position is easy to identify and not subject to debate. Furthermore, as ratings change rather

26. Lev Dynkin, Jay Hyman, and Vadim Konstantinovsky, "Sufficient Diversification in Credit Portfolios: Balancing Two Approaches," *Barclays Capital* (January 2011).

slowly, the guidelines are stable, and the manager is not forced to churn the portfolio as markets move.

Conversely, spreads can react more quickly to market events. As a particular issuer deteriorates in credit quality, the spread-based indicator will typically register that risk has increased much faster than the ratings-based indicator. Nevertheless, while this may be a clear advantage as far as measuring risk, it is not so clear that it is desirable to require managers to transact on price gyrations; the cost of such a policy could be prohibitive. A strict cap on DTS exposure would have the disadvantage of making the limits dependent on pricing, and could lead to inefficient forced selling.

Consider, for example, a strict implementation of a policy that limits DTS contributions. Say we restrict the maximum DTS contribution to any issuer to be 3.0, and that the manager establishes a 0.5% position in issuer XYZ with a spread of 100 bp and a duration of 5 years, for a DTS contribution of $100 \times 5 \times 0.5\% = 2.5$. If the spread widens out to above 120 bp, the manager would then be required to sell off some of the position to stay within the limits. This simple example highlights a number of difficulties with this arrangement. First, pricing uncertainty can make it unclear whether a given position is within the guidelines or not. Second, the need to adjust positions as spreads change represents both an undue hardship for managers and an increase in transaction costs for investors.

Another difficulty with a policy based exclusively on DTS contributions is that it can potentially allow very large exposures to short-dated corporates. While the risk of such a position may not be large in terms of spread volatility or excess return volatility, it is clearly undesirable from a tail-risk point of view. A prudent approach to tail risk is to limit the overall portfolio exposure to any single event.

Nevertheless, it is hard to ignore the evidence that credit ratings do not always present the full picture. The broad-brush treatment that allows the same position size for all A-rated issuers, even while large differences in spreads exist across this peer group, clearly leaves room for improvement. There is no question that incorporating information on issuer DTS contributions gives an improvement in our ability to estimate issuer risk. The difficulty is in setting up rules or guidelines that can incorporate this information without requiring unreasonably high turnover. With some ingenuity, it might be possible to reap the benefits of DTS-based risk controls without imposing too much of an operational burden. For example, one could establish a two-tiered constraint with different thresholds for new and existing positions. For instance, in the above example, if the DTS contribution limits were set at 3.0 for new purchases and 4.0 for existing positions, the XYZ position would remain within the guidelines unless the spread widened out from 100 to beyond 160. Presumably, the requirement to reevaluate the exposure to an issuer after a spread move of this magnitude would not be perceived as overly intrusive.

A more difficult challenge for a system of limits on issuer DTS contributions would be a generic rise in corporate spreads, as was seen in 2008. In this crisis environment, it is likely that virtually every issuer in the credit portfolio would

exceed the previously established caps on issuer exposures. Would we want to force managers to massively rebalance the portfolio into a market with no liquidity?

In general, forced selling is undesirable, and should be avoided whenever possible. We have conducted empirical studies of the performance impact on corporate bond indices of the forced selling of bonds downgraded to below investment-grade.[27] These studies show that investors would be better served by holding on to "fallen angels" well beyond the downgrade, as on average they tend to eventually recoup the overly large losses that they experience as IG managers are forced to sell all at once. How might these results apply to a policy of selling upon a spread widening, even without any change in ratings? This is not at all clear. One might argue that this could help reduce the losses from eventual downgrades; or, conversely, that this would just serve to lock in losses in many bonds that will recover immediately and never suffer a downgrade. Generally, a momentum strategy like this one will do well in trending markets and poorly in choppy markets.

Even when DTS limits are in place, one would probably want to include a hard limit on market value weights, to make sure that no truly large concentrations exist in the portfolio, even in very short-dated or low-spread securities.

In short, we would recommend that for specifying hard limits on issuer exposures within a portfolio mandate, plan sponsors should retain the time-honored tradition of market-weight limits. However, we also believe that managers should track and control the DTS exposures to issuers, and ensure that no single exposure grows too large. Rather than implementing this rule via a hard cutoff beyond which sales would be mandated, managers should have a roughly defined upper limit for issuer DTS exposures, and use their judgment in managing these exposures according to market conditions.

MODELING: CALIBRATING CREDIT-RISK FACTORS

Many portfolio managers rely on multifactor risk models to help them measure and control portfolio risk, either in absolute terms or relative to a benchmark. The DTS approach is ideally suited to estimate spread risk in such models. For example, a risk model might contain modules for measuring exposures to three different types of adverse credit events: systematic changes in spreads, either market-wide or across a particular sector; issuer-specific spread changes; and

27. Kwok Yuen Ng and Bruce Phelps, "Capturing Credit-Spread Premium: Alternative Benchmarks for Credit Investors," *Barclays Capital* (June 2010). This article traces the effect on credit index excess returns of rules that drop bonds immediately after downgrades to high-yield. Indices and other forced sellers incur significant losses on such bonds but never enjoy the benefits of a subsequent recovery. Also see Arik Ben Dor and Jason Xu, "Fallen Angels: Characteristics, Performance and Implications for Investors," *Journal of Fixed Income* (Spring 2011), pp. 33–58. This article studies the price dynamics of fallen angels over a three-year period around the downgrade date.

defaults. The use of DTS can improve the modeling of the first two of these three types of credit risk.

Exposures to systematic changes in credit-spreads in a particular market segment can be measured as the sum of the DTS contributions of all portfolio investments within that segment. The risk factor that relates to these exposures is a relative shift in spreads across the sector; for example, that all financial spreads increase by 10% of their current levels. The alternative to this, in a model not based on DTS, would be to assume that the risk factor is a parallel shift in spreads across a sector (e.g., all financials widen by 10 bp), and that the exposures are therefore contributions to spread duration. Thus, in the DTS-based model, the key risk factor volatility for a particular sector would be its estimated volatility of relative spread changes, as shown in Eq. (55–4) earlier in this chapter, while the alternative model would estimate the volatility of absolute spread changes as per Eq. (55–3).

The DTS-based approach offers three distinct advantages. First, it offers a better assessment of the relative risks of different portfolios. If two portfolios have the same market weight and average spread duration in a given sector, but portfolio A implements this allocation with higher-spread assets than portfolio B, only the DTS-based model will correctly show that portfolio A has a greater exposure to a widening across this sector than does portfolio B. Second, the DTS-based approach improves the accuracy of the risk projection by reducing the uncertainty in the estimation of risk factor volatilities. As we have seen, relative spread volatilities are much more stable than absolute spread volatilities. Therefore, even if we do continually update our estimates of relative spread volatilities within each sector, we find that they change much more slowly than the corresponding estimates of absolute spread volatility and that they are less sensitive to the choice of the time window used in this estimation process.

The third advantage offered by DTS is perhaps more subtle, but opens the door to the most profound change in the structure of the model. Up to this point, we have discussed the exposure to "a given segment of the market" in the abstract, without specifying exactly how the market is to be partitioned. However, choosing the partition along which to measure systematic exposures is one of the most critical elements of risk model design, involving careful tradeoffs among various goals. It is desirable to limit the model to a small number of intuitive factors, both to maximize the clarity and practical applicability of the risk reports produced and ensure that a sufficient number of bonds are available to accurately calibrate each risk factor. Conversely, it is important to include enough factors to achieve sufficient explanatory power. For example, a single risk factor that measures portfolio exposure to U.S. corporates would measure the effect on the portfolio of a potential rally or decline across the corporate bond universe, but not the effect of a relative widening of financials versus industrials. We would like to partition the universe finely enough to capture all major sector rotation effects.

When constructing a model of systematic spread risk for U.S. corporates prior to the introduction of the DTS model, we partitioned this universe into a sector/quality grid, using nine industry groups and three levels of credit ratings for a total of 27 risk factors.[28] The partitioning by quality was made absolutely necessary by the assumption that the systematic spread movement in a given market cell tends to take the form of a parallel shift in spreads. When we calibrated such a model to market data, we found that the volatility of absolute spread changes for Baa financials was much greater than that of Aa financials. Although the risk factors representing these two cells might be highly correlated, the substantial difference in volatilities precluded us from combining these cells.

If we instead assume that the spread change across an industry is a relative shift, we find that we no longer need to segregate our model by credit quality. The fact that Baa financials tend to have greater risk than Aa financials is reflected in the higher spreads. This will show up in the risk model as a larger exposure to the same risk factor based on relative spread volatility, rather than as an exposure to a different risk factor with greater (absolute spread) volatility. This puts the risk model designer at a great advantage with regard to the tradeoff between compactness and explanatory power. The model can be designed with roughly the same explanatory power as before using a much smaller number of risk factors, or we can use a finer industry breakdown to create a model with a similar number of factors but greater explanatory power. We have chosen the latter approach in our modeling efforts, increasing the level of sector detail to recognize 27 distinct industry groups.[29]

KEY POINTS

- Spread volatilities—both systematic and nonsystematic—tend to be proportional to spreads. This empirical observation, with theoretical backing, has many applications to credit portfolio management.
- Forecasts of spread volatility that combine long-term historical estimates of relative spread volatility with current spread levels are more accurate than historical estimates of absolute spread volatility, and are quicker to adapt to changing market conditions.
- Estimates of market beta based on DTS ratios form better projections of future market beta than those based on past observations of empirical market beta.

28. "The Global Risk Model: A Portfolio Manager's Guide," Chapter 26 in Lev Dynkin, Anthony Gould, Jay Hyman, Vadim Konstantinovsky, and Bruce Phelps, *Quantitative Management of Bond Portfolios* (Princeton, NJ: Princeton University Press, 2007).
29. A detailed exposition of a multifactor risk model in which credit is modeled using the DTS approach may be found in Chapter 47 of this volume.

- Matching index exposures to DTS is a better way to form index-replicating portfolios than matching exposures to market weight or contributions to spread duration. For active managers, credit sector overweights and underweights should be specified and implemented in terms of DTS exposures.
- Measuring and controlling DTS exposures to individual issuers can be viewed as an alternative or a supplement to issuer limits based on market weights and credit qualities.
- Portfolio risk models for fixed income can improve model accuracy and robustness by incorporating the DTS approach to project the risk entailed in both systematic sector overweights and in portfolio concentrations in individual issuers.

CHAPTER
FIFTY-SIX

INVESTING IN DISTRESSED STRUCTURED CREDIT SECURITIES

ALFRED MURATA, PH.D., J.D.
Executive Vice President
Pacific Investment Management Company

The structured credit market encompasses securities backed by a wide range of assets. Structured credit securities are often secured by residential mortgage loans, commercial mortgage loans, student loans, credit card loans, auto loans, corporate loans, or other structured credit securities. Nevertheless, there are numerous structured credit securities that are backed by more idiosyncratic collateral types such as aircraft, shipping containers, railcars, restaurant franchise right cash-flows, tobacco tax revenues, airport fees, and small business loans. In a buoyant market, a strategy of investing in distressed structured credit securities may not be feasible, but a fixed income investor should be sufficiently familiar with the strategy to take advantage of the opportunity, should it present itself. This chapter discusses the distressed residential mortgage investment strategy in detail, which is a subset of the distressed structured credit securities investment strategy. Ideas from the distressed residential mortgage investment strategy can often be applied to investments in other sectors of the structured credit market.

BACKGROUND

The unprecedented decline in residential housing prices shifted the bulk of the existing universe of nonagency (not guaranteed by any agency of the government such as Fannie Mae, Freddie Mac, or Ginnie Mae) mortgage-backed securities to the distressed market by the end of 2007, leading to a development of a distressed mortgage-backed securities investment strategy.

Nonagency mortgage-backed securities are created by aggregating the cash-flows from a pool of mortgage loans into a trust and distributing these cash-flows

The author expresses his gratitude for the insights provided by Chris Dialynas.

between various tranches according to predetermined rules. Securities that have the highest priority in the cash-flow distribution waterfall (and consequently are least exposed to credit risk) were sold to risk-averse buyers (such as banks, insurance companies, and money managers), which were willing to accept a lower yield to purchase the securities. In addition, an important factor in the purchase decision of the more risk-averse buyers was the fact that these securities were typically rated AAA by a nationally recognized rating agency (such as Moody's, S&P, or Fitch).

By 2010, national housing prices had declined by 29% from the peak, and mortgage credit performance had significantly underperformed original expectations (from the time of deal origination, where a stress scenario housing price assumption typically assumed flat housing prices). In fact, performance was so poor that even the most senior tranches of most securitizations that were created in 2006 and 2007 have now suffered partial principal writedowns or are expected to sustain partial principal writedowns in the future.

As the rating methodologies of Moody's, S&P, and Fitch all require that a bond that suffers any writedown at all (even if 99.99% of the principal is paid back at par) be downgraded to CCC or lower, the vast majority of the nonagency mortgage-backed securities that were issued in 2006 and 2007 have now been downgraded to CCC or lower by all rating agencies. Rating agency downgrades of nonagency mortgage-backed securities are important because many investors (including many of the largest banks, insurance companies, and money managers) are explicitly prohibited from either purchasing or holding securities once the rating agency ranking has been downgraded below a certain threshold. In addition, even if an investor is not constrained by rating agency ranking (e.g., hedge funds or distressed funds), bonds with lower rating agency ranking tend to finance on poorer repo terms, thus reducing the levered yield for such securities.

Consequently, the plunge in residential housing prices not only had a negative fundamental impact on nonagency mortgage-backed securities (due to the impact of defaults on the underlying mortgage loans, leading to principal writedowns), but also had a very significant negative technical impact on the marketplace (due to forced selling from ratings constrained investors). The forced selling from ratings constrained investors resulted in a decline in market trading levels. Following this price decline, many levered investors were hit by margin calls, leading to further forced selling (even from investors that were not ratings constrained), resulting in a self-sustaining decline in market trading levels. In addition, unlike many niche sectors of the investment universe, there was no large distressed buyer willing to take advantage of the forced selling.

To begin with, the nonagency mortgage-backed security marketplace is very large ($1.4 trillion par as of year-end 2010), and reasonably complicated (especially for nonpractitioners). In addition, since almost all market participants that understood how to analyze nonagency mortgage-backed securities already viewed nonagency mortgage-backed securities to be very "cheap" well before the trough in prices had been reached, there were very few investors who had the combination of capital, credibility, and knowledge of how to analyze nonagency

mortgage-backed securities to stand in the way of the forced selling. At the nadir in early 2009, senior pass-through securities backed by 2006 or 2007 vintage prime ARM collateral (which were originally sold around par) had plunged to the high $40s (per $100 par). Subsequently, the market rallied, such that these bonds traded in the $80 area (per $100 par) by the end of 2010.

ECONOMIC (CREDIT) RISK VERSUS FINANCIAL (LEVERAGE) RISK

Cash-flows from each of the underlying mortgage loans are distributed among the various tranches according to a prespecified cash-flow distribution waterfall. Note that it is likely that with a pool of even the lowest quality mortgage loans, at least some cash-flow will be generated, while with a pool of even the highest quality mortgage loans it is possible that one loan could default and sustain a loss (and thus the pool as a whole would suffer a loss). Consequently, by adjusting cash-flow priorities and deal structure it is possible to create very safe bonds from even the riskiest collateral, and to create risky bonds from even the safest collateral.

An investor in nonagency mortgage-backed securities has two main methods to increase returns—either take economic (credit) risk, or take financial (leverage) risk. Employing either strategy will increase the investor's returns in the event of a favorable scenario, at the expense of a reduced return in a negative scenario. An investor taking economic (credit) risk will purchase nonagency mortgage-backed securities either backed by weaker underlying collateral (i.e., bonds backed by subprime collateral instead of bonds backed by prime collateral), and/or securities that have less structural protection (i.e., less senior in the cash-flow waterfall). In contrast, an investor that takes financial (leverage) risk will borrow funds (either explicitly in the repo market, or implicitly in the derivatives market) and use the borrowed funds to purchase additional securities.

In an environment in which mortgage credit performance deteriorates (which is most likely caused by a decline in housing prices or reduced availability of mortgage credit), a strategy of taking mortgage credit risk may result in poor returns, as voluntary prepayments are lower than expected and defaults are higher than expected. In contrast, a strategy of employing financial leverage risk may produce attractive returns if reasonable access to repo funding is maintained, mark-to-mark price declines are not so large as to cause forced selling and the deterioration in mortgage credit performance is not sufficient to negatively impact the cash-flows of the higher-quality bonds in the portfolio that is employing financial leverage instead of credit risk. On the other hand, in an environment in which financial conditions deteriorate (even if the circumstances are not related to the state of housing market), a combination of reduced repo availability and mark-to-market price declines may lead to margin calls and forced selling (leading to very poor performance for a strategy based on financial leverage). Note that by buying securities that are less senior in the cash-flow waterfall, an investor is in effect locking in nonrecourse term funding on the investment, with the funding rate

being the hold-to-maturity yield of the more senior bonds in the waterfall, and the investment being the tranche that was explicitly purchased, plus all of the tranches which are more senior in the cash-flow waterfall.

ANALYSIS OF NONAGENCY MORTGAGE-BACKED SECURITIES

Analysis of nonagency mortgage-backed securities can generally be divided into three main categories: (1) analysis of the underlying mortgage loans; (2) analysis of the servicing, which can impact cash-flows that are received from underlying mortgage loans; and (3) analysis of the deal structure whereby the cash-flows from each of the underlying mortgage loans are divided among the various securities. All three types of analysis must be completed to formulate an informed investment decision.

Analysis of Residential Mortgage Loans

Analysis of residential mortgage loans involves a review of various attributes for each of the underlying mortgage loans backing the mortgage-backed security, with the end goal of generating a vector of prepayment, default, loss severity, and delinquency rates for each of the mortgage loans in the pool under a variety of scenarios. While one is often tempted to simplify the analysis by assuming that the pool consists of one loan with the "average" of the characteristics of each of the underlying loans, such a simplification could lead to erroneous analysis due to the nonlinearity of various loan characteristics on the likelihood of default and prepayment. For example, a mortgage pool with two loans, each with a loan-to-value ratio of 80%, likely has a much lower loss expectation than another mortgage pool with two loans, one with a loan-to-value ratio of 60%, and the other with a loan-to-value ratio of 100% (since the likelihood of default increases dramatically as the amount of equity that a borrower has in his or her property declines). Consequently, the ability to separately analyze each mortgage loan in the pool will lead to much more accurate results than simply lumping all of the loans together and considering the pool of loans to be the "average" mortgage loan.

Predicting mortgage loan voluntary prepayment, default, loss severity, and delinquency rates will depend upon various mortgage loan characteristics. Mortgage loan characteristics can generally be divided into three main types: (1) static loan characteristics, (2) dynamic loan characteristics, and (3) economic drivers. Static loan characteristics are various data that are obtained at the time of the loan origination, such as credit score, debt-to-income ratio, loan-to-value ratio, lien position, combined loan-to-value ratio (the loan-to-value ratio if all mortgage loans encumbering the property are included), original loan size, zip code, etc. Dynamic loan characteristics are observed subsequent to the loan origination, and include loan dependent information such as delinquency status, refinance incentive, and mark-to-market loan-to-value ratio. Economic drivers are factors which are observed

subsequent to loan origination, which can affect numerous loans; such drivers can include regional housing price changes and mortgage rates.

By reviewing historical data, one can construct a mortgage credit model that can predict voluntary prepayment, default, loss severity and delinquency rates for each loan in a mortgage loan pool under various economic scenarios. Although in theory it may appear to be relatively simple to formulate a mortgage credit model, it is difficult to do so in practice. Note that there are numerous variables to consider, many variables appear to change at once (making it difficult to calibrate the model), and there are numerous problems with the data itself (either due to misreporting on the part of participants in the mortgage origination process, or differences in reporting by issuer). Furthermore, given the large data sets to be analyzed (millions of loans, with numerous data for each month of historical performance data), it may be necessary to employ specialized computer systems such as grid computers with hundreds of microprocessors in order to compute model projections within a reasonable time period. In addition, as a mortgage credit model's foundation is historical data, one should also use model projections with caution, especially when attempting to predict what will happen in scenarios that are significantly different from what has happened before (given the ever-increasing likelihood of unanticipated actions in such scenarios, such as governmental public policy activity).

Analysis of Residential Mortgage Loan Servicing

The servicer's role in a mortgage-backed security transaction is to collect the cash-flows from the underlying mortgage loans. Servicers are generally paid a fee on a monthly basis, which is calculated as a percentage of the loan balance being serviced, regardless of what tasks the servicer actually performs. In an environment of increasing housing prices with few delinquencies, the servicer has a relatively simple task, essentially receiving checks from borrowers and cashing them. On the other hand, in a declining housing price environment with skyrocketing delinquencies, the cost of servicing will increase dramatically as the servicer will need to absorb increased costs of collection procedures. In addition to the increased costs of collection when loans become delinquent, servicers are generally required to advance contractual interest and principal payments to the trust (even for delinquent loans). Even though the servicer is entitled to recoup the advances when the loan is liquidated, a capital constrained servicer may have liquidity pressures if the percentage of delinquent loans in its servicing portfolio increases.

Pursuant to deal documents, servicers usually have a duty to maximize the present value of cash-flow to the trust when making servicing decisions. Nevertheless, deal documents typically provide the servicer with wide latitude in determining which decisions maximize present value. The vast majority of mortgage loans in nonagency mortgage-backed securities transactions are serviced by affiliates of large banks. In addition to servicing a particular mortgage loan in a mortgage-backed securities transaction, the bank may have originated the mortgage loan,

invested in securities backed by the mortgage loan, or may own a second lien mortgage that is subordinated to the first lien mortgage in the mortgage-backed securities transaction. Consequently, the servicer may have an incentive to operate in a manner that maximizes their recovery at the expense of other investors.

Given the substantial decline in home prices and skyrocketing delinquency rates, there have been substantial public policy developments attempting to direct servicers to "keep the borrower in the house," and only foreclosing on the property as a last resort. One way to attempt to keep the borrower in the house is to modify the mortgage loan in order to reduce the likelihood that the borrower will default.

Loan modifications can take many forms. When the housing market was buoyant, a common type of loan modification was a loan capitalization. Under a loan capitalization, delinquent mortgage payments are added to the loan balance, and the borrower was deemed to be current (although would now have a larger mortgage balance to repay). This type of loan modification works well if the borrower became delinquent as a result of inadvertently forgetting to make their mortgage payment, or had a temporary (and now resolved) interruption in income (as the borrower has the ability and willingness to pay, and the loan capitalization places the borrower back into current status and allows them to resume making mortgage payments).

In an environment in which housing prices plunge and the economy weakens, the main causes of delinquency are an inability to afford the required payments (if for example the homeowner loses his or her job), or an unwillingness to pay (if the borrower has a negative equity position in the property). A loan capitalization modification does not resolve these more serious drivers of ability to pay and willingness to pay. Consequently, interest rate reduction modifications (reducing the interest rate on the mortgage) or principal forgiveness (reducing the principal balance of the mortgage) modifications have proved to be more successful at keeping the borrower in the house than loan capitalization modifications.

Due to the servicer's expanded involvement in the resolution of delinquent loans, as the performance of the mortgage pool deteriorates, bond cash-flows (and hence bond valuation) become increasingly sensitive to servicing practices. Given the fact that a servicer's profitability has a very tenuous relationship with a mortgage-backed securities investor's returns, when making investment decisions, one must be cognizant of the conflicts of interest between those of a servicer and those of a mortgage-backed securities' investor when making investment decisions.

Analysis of Deal Structure

Nonagency mortgage-backed securities are created by aggregating the cash-flows from a pool of mortgage loans into a trust and distributing these cash-flows between various tranches according to predetermined rules. Given the fact that there are thousands of nonagency mortgage-backed security deals, each with its

own cash-flow waterfall, many market participants use third-party cash-flow modeling systems that project the distribution of cash-flows between the various mortgage-backed security tranches when provided with loan-level, group-level, or deal-level voluntary prepayment, default, loss severity, and delinquency assumptions. While such third-party cash-flow modeling systems are generally accurate, there have been numerous cases in which cash-flows have not been modeled correctly, often leading to a material impact on bond valuation. Consequently, it is extremely important to carefully review deal documents and verify that the modeled cash-flows are consistent with the deal documents before executing trades.

An Illustrative Example

We now discuss the analysis of a sample nonagency mortgage-backed security, a super-senior tranche, backed by negative amortization adjustable-rate mortgages.

Exhibit 56–1 highlights the deal structure of the bond. One can observe that there are numerous A tranches, with an A included in the tranche name (i.e., 1A1, 2A1, etc.). These A tranches, were originally rated AAA, and are senior in loss allocation priority to the M tranche, which is senior in loss allocation priority to the B tranches (which have a B in the tranche name—B1, B2, etc.). Given the weak performance of the collateral pool to date, losses have been higher than expected. As a result, many of the subordinate tranches have now been written off. The B2, B3, B4, and B5 tranche have been completely written off as a result of the losses that have been realized to date. Future losses on the underlying collateral will now be used to write down the B1 tranche, after which subsequent losses will result in writedowns on the M tranche before the A tranches begin to suffer writedowns.

Although all of the A tranches are senior in the loss allocation priority to the M and B tranches, there are also differences in loss allocation priority between the A tranches themselves. First, there are three different pools of collateral. Cash-flow (and losses after the M and B tranches have been written off) from pool 1 is usually distributed between the 1A tranches (1A1, 1A2, etc.), cash-flow (and losses after the M and B tranches have been written off) from pool 2 is usually distributed between the 2A tranches (2A1, 2A2, etc.), while cash-flow (and losses after the M and B tranches have been written off) from pool 3 is usually distributed among the 3A tranches (3A1, 3A2, etc.). Second, by reviewing deal documents, one can observe that the 2A3 tranche is senior in loss allocation priority to the 2A4 tranche, which is senior in loss allocation priority to the 2A5 tranche, which is senior in loss allocation priority to the 2A6 tranche. In fact, given the substantial credit protection provided by more junior tranches in the capital structure, if losses were to be realized immediately, collateral losses would need to amount to 40.9% of the outstanding collateral balance before the 2A3 tranche even absorbs $1 of loss. Listed in the table next to the tranche name is a percentage number called the credit support percentage, which refers to the percentage

of collateral losses that would need to be sustained before the bond begins to sustain losses.

Despite the 40.9% credit support, the 2A3 bond is still at risk of suffering a principal writedown. First, although the 2A3 bond has 40.9% credit support (assuming all losses occur immediately), principal is allocated between the senior bonds on a pro-rata basis, meaning that the credit support provided by the 2A4, 2A5, and 2A6 tranches is materially reduced if the losses occur over time instead of immediately. Second, given the substantial decline in housing prices since the loans were originated, collateral performance is substantially worse than originally expected.

Exhibit 56–2 shows a distribution of mark-to-market combined loan value ratio of each of the loans in the pool. The combined loan-to-value ratio (CLTV) is the sum of all mortgage debt encumbering the property (first lien plus all junior liens) divided by the market value of the property. In addition, to a current distribution of the mark-to-market combined loan to value is included a projection of what the distribution of combined loan-to-value ratios will be one and two years from now. In aggregate, 76% of borrowers currently have negative equity in the property. Given an expectation of declining home prices over the next year, it is expected that 81.2% of borrowers will have negative equity in their property one year from now. In the following year, a modest increase in housing prices is expected, resulting in 80.2% of borrowers expected to have negative equity in their property two years from now.

The underlying loans in this pool are negative amortization adjustable rate mortgages. Pursuant to the terms of these mortgages, for the first five

EXHIBIT 56–2

Sample Bond Combined Loan-to-Value Distribution

years, borrowers were permitted to make minimum monthly mortgage payments, which in many cases were not sufficient to even cover the interest that was accruing on the mortgage loans. In the case that the monthly payment was not sufficient to cover the interest accruing on the mortgage loan, the difference was added on to the existing mortgage balance, meaning that the outstanding principal balance increased over time, instead of decreasing. In conjunction with a declining housing market, the fact that mortgage principal balances on these loans were increasing had a substantial negative impact on mortgage credit performance. As a result, 54.6% of borrowers are now two or more payments delinquent on their mortgage.

Exhibit 56–3 provides a few summary data points regarding the collateral performance of the pool. One can note that the weighted average current combined loan-to-value ratio is currently 130%, a significant increase from the 77% combined loan-to-value ratio at the time that the loans were originated. As previously discussed, the main drivers of the increase in combined loan-to-value ratio are the substantial decline in home prices since deal inception and negative amortization on the underlying loans. Other noteworthy data from the table is the very low voluntary prepayment rate (a prepayment rate of 1% corresponds to a rate at

which 1% of loans voluntarily prepay a year) and a very low constant default rate (a constant default rate of 1% means that 1% of loans default a year). Note that 54.6% of loans are currently two or more payments delinquent on their mortgage, so it is likely that the constant default rate will have to increase substantially to liquidate this backlog of delinquent loans.

Exhibit 56–4 is an excerpt from what is called a yield table, which shows the yield of the bond in various scenarios (as a function of voluntary prepayment, default and loss severity assumptions), at an assumed purchase price of $62 (per $100 par). In practice, an investor would use a yield table with a much wider range of scenarios (which would then be difficult to display). In addition, yields assuming flat interest rates, and yields assuming that interest rates follow the interest rate forward curve are provided. Note that in the base case (of an assumed 0.5% CPR, 16% CDR, and 68% loss severity for life), 84.8% of remaining loans in the pool default, yet the bonds still provide a yield-to-maturity of 7.66% (when run assuming that interest rates follow the interest rate forward curve). This base case also incorporates a relatively conservative assumption that 7.95% of principal is forgiven due to loan modifications, yet these modifications lead to improved collateral performance. While projected default rates may appear to be high relative to recent experience, one must consider the fact that 54.6% of the loans in the pool have missed two or more payments, and that default rates will have to increase in order to liquidate the backlog of delinquent loans in the pool. One can note (as expected), that bond yields tend to decrease as default rates increase, and the bond yields tend to decrease as loss severity rates increase. Further note that bond yields are significantly higher when the forward interest rates (instead of static interest rates) are assumed.

While the yield table is useful in terms of providing a summary of bond yields in various scenarios, one needs to be cognizant of two main limitations. First, the table shows yields in scenarios in which the voluntary prepayments, defaults, and loss severity are constant—in reality it is likely that these factors will

vary over time. While it is possible to construct yield tables in which prepayment rates, etc. vary over time, it will likely make the yield table very difficult to understand. Second, as previously discussed, there may be significant dispersion in the characteristics of the underlying loans. Assuming a certain prepayment rate, etc. for the pool as a whole, in essence summarizes the loan characteristics of the pool down to the loan characteristics of the "average" loan. While this may be reasonable in certain cases, it may lead to significant errors in other cases.

KEY POINTS

- An investor in nonagency mortgage-backed securities has two main methods to increase returns—either take economic (credit) risk or take financial (leverage) risk.
- Analysis of nonagency mortgage-backed securities can generally be divided into three main categories: (1) analysis of the underlying mortgage loans; (2) analysis of the servicing, which can impact the cash-flows that are received from the underlying mortgage loans; and (3) analysis of the deal structure whereby the cash-flows from each of the underlying mortgage loans are divided among the various securities.
- Analysis of residential mortgage loans involves a review of various attributes for each of the underlying mortgage loans backing the mortgage-backed security, with the end goal of generating a vector of prepayment, default, loss severity and delinquency rates for each of the mortgage loans in the pool under a variety of scenarios.
- The servicer's role in the mortgage-backed security is to collect the money from the underlying borrowers. Due to the servicer's expanded involvement in the resolution of delinquent loans, as the performance of the mortgage pool deteriorates, bond cash-flows (and hence bond valuation) become increasingly sensitive to servicing practices. One must be cognizant of the conflicts of interest between those of a servicer and those of a mortgage-backed securities' investor when making investment decisions.
- Nonagency mortgage-backed securities are created by aggregating the cash-flows from a pool of mortgage loans into a trust and distributing these cash-flows between various tranches according to predetermined rules. It is extremely important to carefully review deal documents and verify that the modeled cash-flows are consistent with the deal documents before executing trades.

CHAPTER
FIFTY-SEVEN

HEDGE FUND FIXED INCOME STRATEGIES

ELLEN RACHLIN
Managing Director
Mariner Investment Group, LLC

CHRIS P. DIALYNAS
Managing Director
PIMCO

VINEER BHANSALI, PH.D.
Managing Director
PIMCO

In this chapter, we discuss many of the most popular hedge fund fixed income investment strategies including macro, asset-backed credit, capital structure arbitrage, long/short credit, distressed, basis trading, index arbitrage and correlation trading, and volatility trading. We believe that a solid understanding of macroeconomic conditions, the economic environment, and the influence of policymakers and participants is critical for any robust investment strategy, including fixed income hedge fund investment strategies. Therefore, we begin with a discussion of macro investing fixed income strategies, focused on interest rates and currencies, and then move into further discussion of other strategies that are relative value, arbitrage strategies, as well as long biased ones. The performance of all of these strategies is dependent upon the portfolio manager's ability to take advantage of deviations of asset prices from their fair values. This process requires having analytical tools and a historical context within which to gauge asset price deviations and their potential for corrections. Relative value, asset-backed and arbitrage strategies require more sophisticated valuation tools for the computation of the expected value of security cash flows.[1]

1. For a more detailed discussion of some of these strategies, see Ellen Rachlin, "Fixed Income Arbitrage," Chapter 1 in Izzy Nelken (ed.), *Hedge Fund& Investment Management Securities* (Oxford, UK: Elsevier, 2006).

MACRO INVESTING

All elements of fixed income investing require an understanding of the macroeconomic framework and the macro-political economic environment. The macro initial condition will dictate a growth and price stability bias. The macro policy bias will determine the set of policy choices appropriate to achieve the policy bias objective. The philosophical bias of policymakers, as shown in Exhibit 57–1, will influence the analytical framework with which the initial condition is diagnosed given the existing institutional architecture of the macro economy.

The complex dynamics of the interaction of these considerations will result in a directional bias for many (if not all) of the risk parameters that concern portfolio managers. The interest-rate direction, yield-curve shape, volatility of interest rates, risk spreads, and currency valuation depicted in Exhibit 57–2, along with the corresponding second derivatives of each, are dominated by the dynamics of the macro system.

Many attributes define the macro-political economic environment. The institutional architecture is certainly very important. The institutional architecture is defined by the political, banking, and legal systems. While these bodies may be easily understood conceptually, they morph over time as the political/philosophical bias of the people in charge change as well as changes in the attitude of the general population occur, which can happen much more slowly.

Understanding the philosophical economic bias of each region is vital to anticipating policy and changes in policy. The primary objectives are simple and straightforward. In the United States, the stated objectives are a stable rate of inflation and full employment. The Europeans concern themselves most with price stability. The Chinese seem concerned with internal industrial development via a mercantilist export policy. Each country will have a particular objective at any particular time, and over time the importance of any particular objective will change as conditions change. Moreover, the philosophical bias evolves as a country evolves. In his *Republic,* Plato describes a very plausible evolution of political rule. Among those considered are: democracy, aristocracy, oligarchy, philosopher kings, monarchy, socialism, totalitarianism, and dictatorship. The implications of each are quite important to investment decisions, as are the migration of regime one to another. Exhibit 57–1 characterizes the institutional composition of a few of the many important financial economies. Note the differences among the market participants.

In his *The Role of Monetary Policy* (American Economic Association, 1968), Milton Friedman elaborates on public policy priorities, potential policy choices, and the difficulty of effective implementation.

> To state the general conclusion still differently, the monetary authority controls nominal quantities—directly, the quantity of its own liabilities. In principle, it can use this control to peg a nominal quantity—an exchange-rate, the price level, the nominal level of national income, the quantity of money by one or another definition—or to

Currency	Appreciate	Appreciate	Appreciate	Depreciate

peg the rate of change in a nominal quantity—the rate of inflation or deflation, the rate of growth or decline in nominal national income, the rate of growth of the quantity of money. It cannot use its control over nominal quantities to peg a real quantity—the real rate of interest, the rate of unemployment, the level of real national income, the real quantity of money, the rate of growth of real national income, or the rate of growth of the real quantity of money.[2]

Understanding the Components of the Statistics

The investor should analyze the data in Exhibit 57–3 with an eye to dissecting the aggregated statistics. Understanding the trend of any particular statistic is insufficient. Understanding the distribution of components of the statistic is vital. In this regard it is most important to distinguish between the distribution of debt formation, both public and private, directed to consumption and that associated with investments. It is important to understand the distribution of prices associated with inflation. It is important to understand the components of trade, both exports and imports, associated with consumption and investments. The implications of the distributions are vitally important to predictions of the future and to an inferential understanding of the motivations of policymakers and the public at large. Also vital to the process is an understanding of when policy end points are near and the implications thereof. A microscopic understanding of the data will enable the investor to decide what coefficients to assign to each statistic and to change the coefficients when appropriate.

Armed with the data, although estimates differ somewhat among sources, the philosophical economic political persuasion and institutional architecture, the portfolio manager's challenge is to forecast the various risk parameters, knowing that there is more to economic behavior than statistics. The portfolio manager must also account for regulatory changes, sociological conditions, political risk, and the psychology of the participants. One looks to the markets for inferential valuations that presumably

Unemployment	9.40%	7.50%	5.10%	4.20%

synthesize all of these criteria. After all, money-making is a bet against forward prices. So, forward rates, yield-curves and currency values are all requisite inputs to the portfolio manager's decisions after an assessment of all of the statistics and after an evaluation of all of the political/economic/philosophical judgments.

Big Changes Are Very Important

The price of an asset is simply the intersection of supply and demand. Activist policy institutions like the U.S. Federal Reserve Bank, the European Central Bank (ECB), the Bank of England, and the Bank of Japan have decided to change their status from referee to both player and referee and to engage directly in the markets in such a way that they become price setters. This is a most important fundamental change to capitalism. Direct government interference in capital markets means that prices are less subject to the fundamental macro valuations described herein and more a function of "social" desire of policymakers. This is a gigantic change and during such a change the portfolio manager must consider placing the political, sociological, and philosophical forecasts ahead of the traditional economic forecasts associated with a "capitalist" system.

The Yield Curve

The yield curve is a mapping of interest rates for various lending periods for a particular issuer. The yield-curve shape can vary substantially and changes in the shape of the yield-curve can be an important source of return to the investor. Longer maturities typically yield more because there is more pro-inflation risk and credit risk embedded within them and they are less liquid than shorter maturities. Absent credit risk considerations, longer maturity securities' yields are lowered because of their higher convexity, which takes on greater value when interest rates become more volatile. In Exhibit 57–4 there is displayed two examples of changes in risk from credit to interest-rate (inflation) risk and vice versa. In addition, we observe the proinflation tendency of policy in the United States in Exhibit 57–5.

Creditors generally cannot foreclose on a sovereign issuer. Defaults on sovereign issuers result in "restructuring," in which creditors receive a fraction of their principal back. So, in anticipation of a potential restructuring, rates increase on the sovereign to reflect the increased credit risk. The increase in rates further impairs the sovereign's credit, thereby increasing default probabilities because the interest-rate itself is higher than the rate of sovereign growth; growth that itself is reduced by the higher interest-rate. Moreover, over very long periods, demographic trends become an increasingly important variable if there is a large outstanding debt. Reductions in population growth translate into fewer workers to contribute to debt servicing and increases in the forward population relieve the debt burden.

The sovereign credit default swap (CDS) market is yet another check on the creditworthiness of the sovereign and the change in the credit status. The CDS market is one in which investors can buy and sell insurance on sovereign credit.

EXHIBIT 57–4

Evolution of Interest-Rate Risk

A policy is triggered and the insurance collected if and only if a default occurs or a restructuring, if CDS contract so specifies. The CDS spread is relative to a standardized LIBOR term and should map closely to the yield spread on that sovereign's bond to the same term rate. Technical contract specifications and potential for regulatory interference cause the two spreads to be unequal. However, the direction of the spreads should be consistent most of the time.

Economic inferences and dynamics, forecasts for interest rates and currencies are, as discussed, much more complex in a highly globalized world economy. Traditionally, currency forecasting was a function of interest-rate differentials,

EXHIBIT 57–5

U.S. Inflation Policy

growth and inflation, trade and capital flows, differentials and purchasing-power parity. Post the 2008 financial crisis, there has been an increasing focus on the growth in relative factor productivity and net trade flows. The military strength of a nation is always a very important consideration.

Many financial economists and investors believe the output gap is an important determinant of inflation. The output gap and inflation are inversely related as the output gap measures the degree of abundance of resources in the economy. The output gap theory relies on empirical Phillips curve analysis, which measures the historical relationship between a most important resource—labor and inflation—as depicted in Exhibit 57–6 for both the United States and the United Kingdom.

EXHIBIT 57–6

Phillips Curve

EXHIBIT 57–7

Implications of Policy Choices

	Capital Controls	Increase Taxes	Reduce Taxes	Inflate	Deflate	Increase Spending	Decrease Spending
Bonds	–	+	–	–	+	–	+
Currency	–	Amb	Amb	–	+	Amb	Amb

+ Buy, – Sell, *Amb* ambiguous.

Currency debasement, inflation, and taxation are all substitute expropriating vehicles in addition to regulatory tools such as capital controls the sovereign has at its disposal. The choice of vehicles is employed in combination with the prevailing conditions shown in Exhibit 57–7 make a big difference to an investor in sovereign bonds and to choice of currency—as always relative to forward values. Exhibit 57–7 is a crude mapping of currency and bond strategy given a particular policy circumstance.

Exhibit 57–8 shows the valuation of a few currencies in both the spot and forward markets. Conceptually, any difference between the interest rates implied by the forwards and the prevailing interest-rate differential between that country and the United States, interest rates (in this case) represents the speculative motive in that market or is indicative of high transaction costs.

Political Self-Interest versus Interest of the Sovereign

Politicians and policymakers can be predisposed to do what is in their best interest as opposed to the national interest. The national interest is, as discussed in the beginning of this chapter, a function of one's underlying political/philosophical/economic beliefs. To the extent that politicians get re-elected by providing benefits to the population through spending programs, we will observe an accumulation of debt and a generalized inflation over time. This has certainly been the case for the United States. Exhibit 57–9 provides inferential support for the thesis that

EXHIBIT 57–8

politics in democratic nations are incentivized to increase debt for the purpose of providing greater benefits to its constituents with the hope of reelection.

Investors in bonds and currencies must consider the psychological impact on policymakers' behavior when legacies are in the making. The period from the 2008 financial crisis through 2011 is a period when legacies are at risk and monumental global financial and social change is proceeding. It is a time for bond and currency investors to evaluate the efficiency of policies, the sustainability of policies, as well as, realistic alternatives to prevailing policies and the implications thereof. Investors should heed the council of notable economists of the past. Specifically, Keynes' policy prescription to a financial crisis might result in, "Euthanasia of the rentier,"[3] and Robert Triffin's concern about the responsibility of the custodians of the reserve currency. "We should be as averse as foreign countries—or more so—to incurring again the awesome political responsibilities and inflationary temptations inseparable from the exorbitant privilege of having our national currency used as the main international currency of the world."[4]

Macro fixed income hedge fund investment is one significant hedge fund style of investing. The rest of this chapter is devoted to other styles including: asset-backed credit, capital structure arbitrage, long/short credit, distressed, basis trading, and index arbitrage and correlation trading.

ASSET-BACKED CREDIT STRATEGY

The asset-based credit strategy is a long/short style of portfolio management that focuses on investing in securitized debt obligations, which may encompass a wide variety of types of debt from residential and commercial mortgages to leases and credit cards. The portfolio manager will seek to identify asset-backed securities that they believe are mispriced relative to the value of the supporting loan collateral for long or short investments. This strategy is focused, generally, on higher yielding securities backed by loans to riskier, non-prime borrowers, but not exclusively so.

The best opportunities to purchase mispriced asset-backed securities generally occur during significant dislocations in the credit markets. Practitioners of this strategy will often develop complex proprietary models to value the individual collateral referencing a given security with the goal of ascertaining whether that security may or may not have a greater liquidation value and principal and interest payment stream than is built into the current pricing. These valuation models will include current information such as payment delinquencies as well as payment projections over the expected life of the security. These models will have the ability to analyze loan level data. Hedging or shorting in

3. Chapter 24 in John Maynard Keynes. *The General Theory of Employment, Interest, and Money* (Cambridge, MA: Harcourt, Brace and Company, 1936).
4. Robert Triffin, "The International Role and Fate of the Dollar," *Foreign Affairs*, 57,2 (1978/79), Council on Foreign Relations.

this strategy may tend to focus on hedging macro risk factors such as general market declines as well as use derivatives on specific vintage or year and seniority in the payment of a securitized obligation.

The types of asset-backed credit collateral considered as a potential investment set for the credit strategy includes agency and non-GSE issued residential mortgage securities, primarily, consumer credit asset-backed securities, commercial mortgage securities, and commercial nonmortgage asset-backed securities, among others. The largest asset-backed credit group, residential mortgages, consists of securities backed by differing mortgage loan types, among them Alt-a, option adjustable-rate mortgages, other subprime loans, as well as others.

These loans are not only securitized into pooled obligations securities, but are further divided into tranches tiered by payment priority loss. The lower the payment priority, the higher the default risk, but also the higher the current yield. Part of this investment strategy is for the portfolio manager to not only identify misvalued securities but misvalued tranches. At times the cheapest security may be the first loss and in other instances it may be the top of the structure. The portfolio manager may also choose to allow their impression of the market environment determine where they are most comfortable in the tranche structure with the view that defaults have a cyclical component.

A portfolio manager may also choose to purchase securities that are "seasoned" meaning that they are older. Borrowers that have been current on their payments, historically, tend to continue to pay. However, seasoned securities tend to be more fully priced and are less likely to be cheap. Short strategies tend to be hedges designed to protect from systematic risks such as against general deterioration in all asset prices, both stocks and bonds and less security level specific, other than derivatives due to the limited ability to short or borrow the cash securities in the asset type.

Some of the underlying collateral that is monitored by the portfolio manager include home and commercial property price appreciation, cumulative default rates, delinquency trends, cumulative loss rates, loss severity from sale, loan to value rates, loan modification levels, liquidation rates, geographic, REO levels, commercial sector demand, and unemployment rates, among others. Because default rates are the primary risk factor in this asset class, the asset-backed credit portfolio manager will monitor the performance of the underlying loans behind the asset-backed securities held and the ones under consideration for possible inclusion in their portfolio. Some details include the number of reference loans that are delinquent, length of time delinquent, nonperforming, in foreclosure and liquidated, as well as restructured and re-performing.

Hedging techniques and possibilities have greatly expanded in scope and potential for this hedge fund strategy over time. At one time, one could only primarily think in terms of hedging systematic or cyclical risk. One would choose broad-based credit, interest-rate or even equity indices to provide downside protection. However, during the beginning stages of the housing debt market crisis a proliferation of derivative products that referenced asset-backed securities and tranches of

asset-backed securities by type were developed that offered ways to more directly hedge or short sell residential and later, commercial asset-backed securities. Some of these products include: Markit ABX-HE, Markit CMBX, Markit TRX.NA, and Markit iBoxx European ABS, as well as credit default swaps on home equity asset-backed securities. These derivatives are tranched, allowing for a more specific type of asset-backed hedge or short sale instrument.

CAPITAL STRUCTURE ARBITRAGE

Capital structure arbitrage is an investment strategy that is typically focused on stressed or distressed companies. Typically, these are ones with high balance sheet leverage. A capital structure arbitrage portfolio manager considers all securities of a company (debt and equity) for possible mispricing or relative mispricing. They view the securities by payment priority against current cash and future earnings potential. They assess value by ascertaining probabilistic ability to pay debt obligations as well as potential realized equity valuation. Capital structure arbitrage is an investment strategy that is flexible and broad enough in scope to accommodate opportunities that arise throughout the credit cycle. For example, the portfolio manager may be more constructive on holding equity that appears cheap versus a senior debt short hedge during an economic recovery and shorting equity while holding senior secured debt during economic contraction. Other times, the financial merit of a company's outstanding securities may hold a case independent of economic times. The portfolio manager will likely identify a specific catalyst event that will correct the senior versus junior security relative value mispricing. This catalyst could be an upcoming refinancing or a business specific event. This strategy tends to use low levels of leverage as the companies invested in have high levels of balance sheet leverage.

The layers of securities within a company can be quite varied from senior secured bank debt with strong covenants to the most junior security or equity-based ones. Each of these securities can be expected to have unique volatility characteristics. The more junior a security, the more likely it will be relatively more volatile. The portfolio manager must consider this volatility when positioning long and short as this will affect the overall P&L volatility exposure to their portfolio.

The portfolio manager must evaluate the covenants of outstanding debt and ascertain payment priority, which can be complicated. The most difficult layer of complication comes from companies with multiple subsidiaries. Subsidiaries and holding companies may have cross-liabilities and not be entirely self-reliant. The portfolio manager must also factor in debt maturity schedules as an important element of valuation against their prediction of future ability to make interest and principal payments. Often the clarification of payment priority and asset rights are resolved in a court of law. The portfolio manager must have a thoughtful way of assessing the likely bankruptcy proceeding outcomes in regard to the various debt instruments outstanding. This process can be fairly long and the outcomes uncertain. However, these securities are usually ones that can be sold or traded long before final legal decisions are reached.

A capital structure arbitrage portfolio is likely to contain multiple positions in various securities within the capital structures of many companies. Each of these companies is likely to be or anticipated to be experiencing some form of structural change as a result of meaningful current or prospective corporate events. The events may not only include a changing capital structure specific to one company, but may represent changing financial fortunes inflicted by the larger macroeconomic environment on many sectors of the economy. Often the capital structure arbitrage portfolio can be concentrated by sector as industry dynamics can affect multiple companies at once in a way that creates opportunity uniquely to that sector. The portfolio manager thinks in terms of various scenarios with probabilistic outcomes. The long and short security weightings will reflect their probabilistic assessments. Longs may hold a larger weight if stronger economic fortunes are expected ahead, for example. Events have varying time frames and the portfolio manager is also likely to assess the attractiveness of an opportunity based on the present value of the expected price change of the securities positioned.

Hedging in this strategy tends to be company specific, whether on a junior or senior security basis. However, it is usual to see industry level hedges or even index based ones in this strategy. Capital structure arbitrage portfolios can have a tendency to be net long for the company specific positions. Other more generalized hedging techniques may often make sense to deploy in order to mitigate overall market beta exposures.

LONG/SHORT CREDIT STRATEGY

The long/short credit strategy is also referred to as a relative value strategy or a fixed income arbitrage strategy. Within any of these descriptions are multiple substrategies or investment approaches practiced. Some of these substrategies may have very specific tightly hedged arbitrages while others have more systemic or generalized hedging approaches. Long/short credit strategies can include debt securities within the entire credit spectrum from investment-grade to high-yield and distressed. All approaches depend upon a bottom-up analysis of a given company's ability to pay its debt obligations based on its business model and its revenue prospects. Similarly, portfolio managers are focused on economic and leverage cycles, which affect companies' abilities to meet their debt obligations. A long/short credit portfolio can consist simply of diverse bond positions both long and short of companies that the portfolio manager feels are worthy of taking a positive or negative view on based on current default probability versus current price. A portfolio manager can be expected to hold overall exposure ranging from net long to closer to market neutral. Practically speaking, it is unusual for a portfolio to be consistently net short.

Cash corporate debt (loans, bonds, and preferreds) and derivatives, both single company reference as well as index and tranches of indices are the main instruments used, in addition to sovereign debt instruments. However, interest-rate

and equity instruments are used to hedge or emphasize certain desired exposures. Specifically, cash corporate debt obligations are ones that have some claim or payment priority in the event of corporate default. Derivative instruments, credit default swaps, are generally bi-lateral payment agreements between two contractual parties based upon the financial fortunes of a referenced entity. These instruments represent no direct obligation of the referenced company in the event of default. These instruments will be assessed based on a given entities' prospective cash flows, asset quality, covenant protection, possible catalysts that may alter an entity's future earnings capabilities, industry trends, overall default rates, credit conditions, industry, and broad economic factors, among others.

The long/short credit portfolio manager may take several different approaches toward building their portfolio. They may construct a credit long book and a credit short book with the net and gross exposures reflecting some macro point of view regarding underlying market volatility and near term direction. In general, the gross market value of the aggregated positions versus assets under management can be expected to be larger for higher rated, lower spread debt than lower rated, wider spread debt. Such construction reflects a risk attitude that the latter is likely more volatile in price.

Directional longs may include the debt or credit derivatives of out of favor, stressed, distressed companies, debt whose prices seem to be below their fair price as assessed by the portfolio manager, or of companies undergoing positive changes. Directional shorts may include the debt of or credit derivatives of companies that are experiencing a cyclical decline, whose prices seem to be above their fair price given future earnings potential as assessed by the portfolio manager, or provide opportunity to profit from the part of the leverage cycle in which all corporate bond spreads are widening. The portfolio manager can be expected to use leverage but hold some reasonable portion of unencumbered or excess cash over their margin requirements. The amount of unencumbered cash held will rise and fall depending on the overall conditions of the markets, both by cyclicality and opportunity. Depending on the risk appetite of the portfolio manager, their portfolio may be highly diversified with hundreds of positions or be more concentrated. Generally, over time the more concentrated a portfolio, the more volatile that portfolio's valuation can be expected to be. Concentration can refer to position size, ownership percentage of a particular debt issue, geography, industry, and credit quality, among others.

Of a given debt issue, the higher its investment rating, the lower the probability of its default; however, the return distribution of such a debt issue will be negatively asymmetrically skewed with more downside potential than upside. This is what makes hedging interesting in this strategy. Hedging can be company specific in such a way that overlaps with capital structure arbitrage and involve other debt in the same company as well as reference credit default swaps. Hedging or shorting can be used to express a negative view on a company or a sector as well as to maintain a net short position during times of market turmoil. Hedging can also be as broad in nature to include generalized equity, credit, and interest-rate hedges.

The more tightly hedged, market neutral or investment-grade focused a given portfolio is, the greater likelihood leverage will be higher than otherwise. Concentrated or net long portfolios can be expected to be commensurately less leveraged, as this type of portfolio will be more volatile than a market neutral one.

DISTRESSED

The distressed investing strategy is one that focuses on investing in the securities of companies experiencing financial stress. They may be or may not be in default. The investment situations may be ones that are meant to focus on improving corporate balance sheets, others may be liquidation investments in which a company's securities may represent a claim on valuable assets, including cash, some liquidity investments in which refinancing will provide the necessary time for a company to recover, or litigation investments in which the portfolio manager may participate on creditor committees and the value of certain securities will be determined in a court of law. As well, some positions may be short ones on deteriorating companies that are losing market share or are cyclical in nature. All positions will generally be constructed with an identifiable catalyst or some event, usually corporate specific, that will unlock the value potential of securities held in the portfolio.

The securities held in the portfolio of a distressed strategy can include all parts of the capital structure of a company, holding company or subsidiary as well as aggregated debt securities as described in the asset-backed security strategy section. Securities range from senior secured debt (such as bank loans) to subordinated debt (such as second lien debt) down to more junior secured securities (such as busted convertibles trading well below the convertible price and equities). Other types of debt securities exist only with companies experiencing financial distress such as debtor in possession (DIP) or rescue financing. The lower the debt in the capital structure or payment priority, the lower the dollar price can expected to be.

The distressed portfolio manager may take several approaches to building their portfolio. This strategy is primarily long-biased and the characteristics of the securities held in a sensibly constructed portfolio will include ones that are the debt or equity of companies that are industry leaders or have strategic importance, ones that are cheap relative to not only current valuation but have a cushion to protect during a downturn or market volatility, and well priced for the industry and region in which the company does business. The portfolio manager may use other companies' valuations in a similar industry to ascertain value of a target company as a way of affirming the total valuation of the securities they are holding. It is worth noting that one aspect of this strategy overlaps with the asset-backed credit strategy in that impaired structured credit such as collateralized debt obligations (CDOs) and collateralized loan obligations (CLOs), which are bundled multiple corporate debt obligations are often part of a distressed portfolio manager's investment set. These securities can be disaggregated to the loan or bond level and valued against current market pricing for the debt obligations of the underlying companies. The portfolio

manager will value the sum of the collateralized obligation against the parts and attempt to profit if there is a suitable mismatch. Overall, the distressed portfolio will be likely constructed of multiple positions in multiple companies, but can be concentrated as when the securities of the top 10 companies represent a majority of the invested assets under management.

Hedging for this strategy will span from other parts of the capital structure in which strategic long positions exist to index or interest-rate hedges. Hedges may also include the debt and equity of other companies within the same or similar industries as strategic long positions. This strategy may also encompass short positions for companies whose fortunes are declining given industry trends and economic outlook. However, in this situation, which can be fairly cyclical by nature, portfolio managers may tend to restrict capital inflows, or even return money to investors if opportunities are scarce. Tactically, portfolio managers can move "up or down" in the capital structure, buying senior secured positions during the weaker part of the economic or industry cycle and taking more junior security positions, unsecured or equity, during growth phases of the cycle. While not necessarily a hedging technique, it is a risk mitigation one.

BASIS TRADING

Basis trading involves the simultaneous purchase and sale of two closely related securities to take advantage of relative mispricing.

In the classic futures basis trade, an investor can buy a cash Treasury security and sell a futures contract. In the credit basis trade, an investor purchases or sells a cash corporate bond and hedges the credit risk by the purchase or sale of credit default swaps. Other versions, such as the LIBOR-fed funds, or its longer maturity counterpart, the swap-spread trade, as well as the cross-currency basis swap, which involves funding in one currency and swapping via the currency forward exchange-rate market are also popular.

The hallmark of all basis trades is the isolation of a factor that is not present in one leg of the trade but is present in the other leg. In the futures basis trade, the important factor is the presence of a delivery option. The gross basis of each bond in the delivery basket is computed by computing the difference in its forward price versus the converted price of the futures contract (the delivery price, which equals the futures price times a conversion factor specified by the exchange). To obtain the net basis the gross basis is adjusted by the net carry, which is the coupon income and re-investment income minus the funding cost or repo rate of the bond. When the net basis is positive, a long cash/short futures basis trade has a negative expected loss equal to the basis. For example, if the net basis is 2/32nds, the long-cash, short futures position is expected to lose 2/32nds if held to the futures expiration date. The reason for negative expected return is that the person who is short the futures contract has an option to deliver one of the bonds in the basket, and the price of the option is equal to the value of the net basis. The short

effectively pays the long futures holder for this option. Since all option values are positively correlated to a rise in volatility, the value of the option can rise if interest-rate volatility rises. In the case of the futures basis trade, the probability of another bond switching to become the cheapest to deliver rises as the volatility rises. Thus a person with the short futures position will have the value of the delivery option rise in an environment of rising volatility. Thus futures basis trading is really an option trading enterprise.

In a cash-CDS basis trades, an investor prefers to purchase a cash corporate bond and buy protection against it using credit default swaps contracts. If cash bond yields are higher than the price of protection, then the investor can take out risk-free profits. Following the history of the cash-CDS trade (here depicted at an aggregate level), illustrates some important insights into the fundamental driving factors. Before the crisis of 2008, the cash-CDS basis traded within a small range around zero. However, the crisis created a substantial widening of the spread, and the basis went negative, that is, cash bonds traded substantially wider than the CDS. In other words, at the height of the crisis an investor who had cash could purchase a cash corporate bond and buy protection on the credit risk and still be ahead by hundreds of basis points from those who did not have the cash and were forced to liquidate the cash bonds. In other words, the cash-CDS corporate basis trade is driven by the important risk-factor of liquidity. When liquidity is ample (as illustrated by the convergence of the basis trade after the infusion of liquidity from the Fed) the spread between cash and CDS quickly falls, as shown in Exhibit 57–10.

EXHIBIT 57–10

Spread between Cash and CDS

INDEX ARBITRAGE AND CORRELATION TRADING

Broadly speaking, index arbitrage and correlation trading take advantage of mispricing between the valuation of an index and its tranches (the "composite" securities), and the weighted valuation of its constituents. Since most indices have a large number of constituents, assumptions have to be made about the correlations between the constituents in order to reduce computational complexity. Thus index arbitrage is also known as "correlation" arbitrage.

The investment-grade credit default swap index (CDX) consists of 125 names of investment-grade credits that are selected by a consortium to represent the universe of investment-grade credits. There are similar indices in high-yield, Europe (ITRAXX), emerging markets, and others that make correlation trading possible. For the purpose of the discussion here, we will look at the CDX (investment-grade) indices.

The CDX index tranche market takes the losses on the 125 names and tranches them. The first tranche is the 0% to 3% or the equity tranche, which takes the first 3% of losses. The next three (mezzanine) tranches are the 3% to 7%, 7% to 10%, and the 10% to 15% tranches, which take the losses from 3% to 7%, 7% to 10%, and 10% to 15%, respectively. Finally the senior and the super senior tranches are defined by the attachment and detachment levels of 15% to 30% and 30% to 100%, respectively. These tranches are thus akin to put spreads on losses on the underlying index.

Correlation trading starts with the observation that if all correlations rise, the likelihood of large losses goes up, since many underlying entities become likely to default. Thus, if correlations rise, the premium that one receives for selling protection on super senior tranches should go up. Similarly, as correlations go up, the equity tranche premia fall, since the possibility of no or low losses also increases. The case for the tranches in the middle (the mezzanine tranches) is much more complicated and typically requires a model. In correlation trading, a portfolio manager takes a view on the correlation, and combines different tranches from the capital structure stack to express their view, while keeping the exposure to the underlying index flat or delta-hedged. Similar to trading equity options by using implied volatility, tranche trading with reference to implied correlations is a popular strategy (with similar shortcomings). For equity options trading, the correlations are implied by fitting a Black-Scholes distribution to the option prices and extracting the value of the implied volatility parameter. For tranche trading, the popular approach is to use a Gaussian copula approach to model the joint behavior of defaults, and take views on the implied correlations.

Correlation trading done with simple models such as these ran into trouble in May 2005, when equity tranches hedged with mezzanine tranches diverged greatly from the model implied numbers. This can be traced to the downgrade of companies in the index that created a steep correlation skew (akin to a volatility put skew that occurs when there is a market crash) to account for higher systemic risk.

VOLATILITY TRADING

Volatility trading focuses on the purchase and sale of implied volatility in the market. In its most direct form, volatility trading attempts to benefit from opportunities and perceived mispricing in the fixed income options markets. Since options prices are primarily determined by the implied volatility of the underlying reference security, a portfolio manager can analyze the opportunity from many different angles.

The first approach is to buy or sell options when the implied volatility is rich or cheap compared with some metric of long-term levels. To do so, portfolio managers use various estimation techniques to measure and forecast realized volatilities. If implied volatilities are higher than the forecast of realized volatilities, options are sold and the risk to the underlying is delta-hedged based on some model. Typically, option prices reflect a risk-premium, since sellers of options require compensation over and above the actuarially fair value of the options in order to sell them. Over long periods of time the average return from selling fixed income options, and holding them to maturity, in particular, has been positive since yields are naturally mean-reverting (high rates slow the economy down and hence cause yields to fall). Many portfolio managers follow the ratio of implied to realized volatilities to wait to initiate these trades. For those who do not want to hedge the risk to the underlying by delta hedging, instruments such as variance and volatility swaps are available where a direct bet on the level of volatility levels can be made in relation to a volatility strike. Of course, this strategy is very directional in both the level of volatility and in the level of rates, since the profit or loss is driven by both movements in the level of uncertainty as well as the demand for options from hedgers.

Another approach to trading volatility is to look at the volatility surface and find opportunities from mispricing of particular strikes, expiries, and maturities. The swaption volatility "cube" is specified in terms of swaption expirations, as well as, the swap "tails" that these swaptions exercise into the different strikes given the option expirations and underlying forward swaps. For instance, with low rates and the short-end of the yield-curve pegged to zero rates, a portfolio manager might take the view that the implied volatility for a payer swaptions (one that gives the right to pay fixed) at a higher strike than current forward is pricing in too much volatility. They can sell that swaption and pick both the volatility premium and the payer skew (currently payer swaption volatilities are higher than receiver swaptions due to inflation hedging demand for high strike payer swaptions).

Many portfolio managers also look at implied optionality across various fixed income securities. For instance, a mortgage backed agency pass-through is sensitive to the change in volatilities since rising volatilities increase prepayment probabilities. A mortgage pass-through buyer is naturally short the prepayment option to the homeowner, and is compensated for the option in terms of extra spread. If the level of swaptions volatilities is low compared with the option volatility implicit in the mortgage security, a portfolio manager can position a volatility arbitrage by buying the MBS and buying the swaption.

A further extension of volatility trading is to execute the trades across markets. One might take the view that option volatility in the United States is higher than European fixed income, and sell options in one versus purchase in another. Or that the volatility expressed in the fixed income options market is higher or lower than the volatility expressed in the longer dated currency options markets. The two are related because currency forwards are driven by both the spot exchange-rate and interest-rate differentials, and for longer dated forwards the volatility and correlation of the longer rates becomes a dominant relative value factor.

KEY POINTS

- All elements of fixed income investing require an understanding of the macroeconomic framework and the macro-political economic environment at any point in time; present and future for any country or region within which the investment is derived. The complex dynamics of the interaction of these considerations will result in a directional bias for many (if not all) of the risk parameters that concern portfolio managers. The interest-rate direction, yield-curve shape, volatility of interest rates, risk spreads and currency valuation, and the second derivatives of each are all dominated by the dynamics of the macro system.
- The asset-based credit strategy is a long/short style of portfolio management that focuses on investing in securitized debt obligations, which may encompass a wide variety of types of debt from residential and commercial mortgages to leases and credit cards.
- Capital structure arbitrage is an investment strategy that is typically focused on stressed or distressed companies. Typically, these are ones with high balance sheet leverage.
- The long/short credit strategy is also referred to as a relative value strategy or a fixed income arbitrage strategy. Within any of these descriptions are multiple substrategies or investment approaches practiced. Some of these substrategies may have very specific tightly hedged arbitrages while others have more systemic or generalized hedging approaches. A long/short credit portfolio can consist simply of diverse bond positions both long and short of companies that the portfolio manager feels are worthy of taking a positive or negative view on based on current default probability versus current price.
- The distressed investing strategy is one that focuses on investing in the securities of companies experiencing financial stress. They may be or may not be in default. The investment situations may be ones that are meant to focus on improving corporate balance sheets; others may be

liquidation investments in which a company's securities may represent a claim on valuable assets including cash, some liquidity investments where refinancing will provide the necessary time for a company to recover or litigations investments where the portfolio manager may participate on creditor committees and the value of certain securities will be determined in a court of law.

- Basis trading involves the simultaneous purchase and sale of two closely related securities to take advantage of relative mispricing. In the classic futures basis trade, an investor can buy a cash treasury security and sell a futures contract. In the credit basis trade, an investor purchases or sells a cash corporate bond and hedges the credit risk by the purchase of sale of credit default swaps.
- Index arbitrage and correlation trading take advantage of mispricing between the valuation of an index and its tranches (the "composite" securities), and the weighted valuation of its constituents.
- Volatility trading focuses on the purchase and sale of implied volatility in the market. In its most direct form, volatility trading attempts to benefit from opportunities and perceived mispricing in the fixed income options markets.

CHAPTER
FIFTY-EIGHT

FINANCING POSITIONS IN THE BOND MARKET

FRANK J. FABOZZI, PH.D., CFA, CPA

STEVEN V. MANN, PH.D.
Professor of Finance
Moore School of Business
University of South Carolina

Leveraging strategies require that an investor borrow funds. There are several well-established arrangements in the bond market for borrowing funds. The most common practice is to use the securities as collateral for a loan. In such instances, the transaction is referred to as a *collateralized loan*. In this chapter we will look at the four types of collateralized loans in which the collateral is a bond: repurchase agreement, dollar roll, securities lending, and margin buying.

A collateralized loan is not the only mechanism available to an investor for creating leverage. Derivative contracts are instruments that allow an investor to synthetically create leverage. This is so because a derivative contract allows an investor to obtain greater exposure to a specific bond issuer per dollar invested than the same dollar amount invested in the cash-market instrument. For example, the initial futures margin that an investor must make to obtain a long position in a Treasury bond futures contract creates an exposure to Treasury bonds much greater than the exposure if that initial futures margin were used to purchase Treasury bonds. In the case of an interest-rate swap, consider the fixed-rate receiver's position. This party is effectively borrowing on a floating-rate basis to obtain exposure to a fixed-rate bond position where the par value of that bond position is equal to the swap's notional amount. Similarly, there are cash-market instruments that have embedded leverage. For example, an inverse floater position is equivalent to borrowing funds on a floating-rate basis in order to obtain a fixed rate.

REPURCHASE AGREEMENT

A *repurchase agreement*, or simply *repo agreement* or *repo*, is the sale of a security with a commitment by the seller to buy the same security back from the purchaser at a specified price at a designated future date. The price at which the

seller subsequently must repurchase the security is called the *repurchase price*, and the date that the security must be repurchased is called the *repurchase date*. Basically, a repurchase agreement is a collateralized loan where the collateral is the security sold and subsequently repurchased.

Suppose that a government securities dealer purchases a 3.125% coupon Treasury note that matures on May 15, 2021 on Tuesday, May 24, 2011. The face amount of the position is $1 million, and the note's full price is $1,001,545.52. Further, suppose that the dealer wants to hold the position overnight. Where does the dealer obtain the funds to finance this position? Of course, the dealer can finance the position with its own funds or by borrowing from a bank. Typically, the dealer uses a repurchase agreement or "repo" market to obtain financing. In the repo market, the dealer can use the purchased Treasury note as collateral for a loan. The term of the loan and the interest rate a dealer agrees to pay are specified. The interest rate is called the *repo rate*. When the term of a repo is one day, it is called an *overnight repo*. Conversely, a loan for more than one day is called a *term repo*. The transaction is referred to as a "repurchase agreement" because it calls for the security's sale and its repurchase at a future date. Both the sale price and the purchase price are specified in the agreement. The difference between the purchase (repurchase) price and the sale price is the loan's dollar interest cost.

Let us return now to the dealer who needs to finance the Treasury note that it purchased and plans to hold for one day. The settlement date is the day that the collateral must be delivered and the money lent to initiate the transaction. Likewise, the termination date of the repo agreement is May 25, 2011. At this point we need to ask, who is the dealer's counterparty (i.e., the lender of funds). Suppose that one of the dealer's customers has excess funds in the amount of $1,001,545.52, called the *settlement money*, and is the amount of money loaned in the repo agreement.[1] On May 24, 2011, the dealer would agree to deliver ("sell") $1,001,545.52 worth of Treasury notes to the customer and buy the same Treasury security for an amount determined by the repo rate the next day on May 25, 2011.[2] Suppose that the repo rate in this transaction is 0.08%. Then, as will be explained below, the dealer would agree to deliver the Treasury notes for $1,001,545.52 and repurchase the same securities for $1,001,547.75 the next day. The $2.23 difference between the "sale" price of $1,001,545.52 and the repurchase price of $1,001,547.75 is the dollar interest on the financing.

The following formula is used to calculate the dollar interest on a repo transaction:

$$\text{Dollar interest} = (\text{dollar principal}) \times (\text{repo rate}) \times (\text{repo term}/360)$$

1. For example, the customer might be a municipality with tax receipts that it has just collected and no immediate need to disburse the funds.
2. We are assuming in this illustration that the borrower will provide collateral that is equal in value to the money that is loaned. In practice, lenders require borrowers to provide collateral in excess of the value of money that is loaned. We will illustrate how this is accomplished shortly when we discuss repo margins.

Notice that the interest is computed using a day-count convention of actual/360 like most money market instruments. In our illustration, using a repo rate of 0.08% and a repo term of one day, the dollar interest is $2.23, as shown below:

$$\$2.23 = \$1{,}001{,}545.52 \times 0.0008 \times (1/360)$$

The advantage to the dealer of using the repo market for borrowing on a short-term basis is that the borrowing rate (i.e., the repo rate) is less than the cost of bank financing. (The reason for this is explained below.) From the perspective of the entity lending funds, the repo market offers an attractive yield on a short-term secured transaction that is highly liquid.

The repo market can be used not only to finance a position in the market but also to cover a short position. For example, suppose that a dealer shorted a bond issue two weeks ago and must now cover the position—that is, deliver the bond issue. The dealer can do a *reverse repo* (i.e., agree to buy the bond issue and sell it back). Of course, the dealer eventually would have to buy the bond issue in the market in order to cover its short position. In this case, the dealer is actually making a collateralized loan to the counterparty.

There are a number of terms associated with repurchase agreements that are used widely. This market-specific vocabulary is discussed in Chapter 16 where private money market instruments are discussed. It is important to be mindful that the transaction is straightforward. One party is lending money and accepting a security as collateral while the other party is borrowing money and providing collateral to do so.

Credit Risks

Repos should be structured carefully to reduce credit risk exposure. The amount lent should be less than the market value of the security used as collateral, thereby providing the lender with some cushion should the market value of the security decline. The amount by which the market value of the security used as collateral exceeds the value of the loan is called *repo margin* or, simply, *margin*. Margin is also referred to as the "haircut." Repo margin is generally between 1% and 3%. For borrowers of lower creditworthiness and/or when less liquid securities are used as collateral, the repo margin can be 10% or more.

To illustrate the role of a haircut in a repurchase agreement, let us once again return to the government securities dealer who purchases a 3.125% coupon Treasury note and needs financing overnight. Recall that the face amount of the position is $1 million, and the note's full price is $1,001,545.52. When a haircut is included, the amount the customer is willing to lend is reduced by a given percentage of the security's market value. In this case, the collateral is 102% of the amount being lent. Accordingly, to determine the amount being lent, we divide the note's full price of $1,001,545.52 by 1.02 to obtain $981,907.37. Suppose that the repo rate in this transaction is 0.08%. Then the dealer would agree to deliver the Treasury notes for $981,907.37 and repurchase the same

securities for $981,909.55 the next day. The $2.18 difference between the sale price of $981,907.37 and the repurchase price of $981,909.55 is the dollar interest on the financing. Using a repo rate of 0.08% and a repo term of one day, the dollar interest is calculated as shown below:

$$\$2.18 = \$981{,}907.37 \times 0.0008 \times (1/360)$$

Another practice to limit credit risk is to mark the collateral to market on a regular basis. (Marking a position to market means recording the value of a position at its market value.) When market value changes by a certain percentage, the repo position is adjusted accordingly. The decline in market value below a specified amount will result in a margin deficit. The BMA Master Repurchase Agreement gives the borrower the option to cure the margin deficit by either providing additional cash or by transferring additional securities that are reasonably acceptable to the lender. Suppose instead that the market value rises above the amount required for margin. This results in a margin excess. In such instances, the BMA Master Repurchase Agreement grants the lender of funds the option to give the borrower cash equal to the amount of the margin excess or to transfer purchased securities to the borrower.

Since the BMA Master Repurchase Agreement covers all transactions where a party is on one side of the transaction, the margin maintenance is not looked at from an individual transaction or security perspective but as all repo transactions with the same counterparty.

The price to be used to mark positions to market is defined in the agreement. The market value is defined as one "obtained from a generally recognized source agreed to by the parties or the most recent closing bid quotation from such a source."

One concern in structuring a repo is delivery of the collateral to the lender. The most obvious procedure is for the borrower to deliver the collateral to the lender or to the cash lender's clearing agent. In such instances, the collateral is said to be "delivered out." At the end of the repo term, the lender returns the collateral to the borrower in exchange for the principal and interest payment. This procedure may be too expensive, though, particularly for short-term repos, because of the costs associated with delivering the collateral. The cost of delivery would be factored into the transaction by a lower repo rate that the borrower would be willing to pay. The risk of the lender not taking possession of the collateral is that the borrower may sell the security or use the same security as collateral for a repo with another party.

As an alternative to delivering out the collateral, the lender may agree to allow the borrower to hold the security in a segregated customer account. Of course, the lender still faces the risk that the borrower may use the collateral fraudulently by offering it as collateral for another repo transaction. If the borrower of the cash does not deliver out the collateral but instead holds it, then the transaction is called a *hold-in-custody repo* (HIC repo). Despite the credit risk associated with an HIC repo, it is used in some transactions when the collateral is difficult to deliver (such

as in whole loans) or the transaction amount is small and the lender of funds is comfortable with the reputation of the borrower of the cash.

Another method is for the borrower to deliver the collateral to the lender's custodial account at the borrower's clearing bank. The custodian then has possession of the collateral that it holds on behalf of the lender. This practice reduces the cost of delivery because it is merely a transfer within the borrower's clearing bank. If, for example, a dealer enters into an overnight repo with customer A, the next day the collateral is transferred back to the dealer. The dealer can then enter into a repo with customer B for, say, five days without having to redeliver the collateral. The clearing bank simply establishes a custodian account for customer B and holds the collateral in that account. This specialized type of repo arrangement is called a *triparty repo*. In fact, for some regulated institutions, for example, federally chartered credit unions, this is the only type of repo arrangement permitted.

The agreement covers the events that will trigger a default of one of the parties (i.e., "events of default") and the options available to the nondefaulting party. In the case of a bankruptcy by the borrower, the bankruptcy code in the United States affords the lender of funds in a qualified repo transaction a special status. It does so by exempting certain types of repos from the stay provisions of the bankruptcy law. This means that the lender of funds can liquidate the collateral immediately to obtain cash.

Determinants of the Repo Rate

Just as there is no single interest rate, there is no unique repo rate. Repo rates vary from transaction to transaction and across time due to a number of factors. These factors include the following: (1) quality of the collateral; (2) term of the repo; (3) delivery of the collateral; (4) availability of the collateral; and (5) the prevailing federal funds rate. These factors are discussed in detail in Chapter 16.

DOLLAR ROLLS

In the mortgage-backed securities (MBS) market, a special type of collateralized loan has developed because of the characteristics of these securities and the need of dealers to borrow these securities to cover short positions. This arrangement is called a *dollar roll*, so-called because the dealer is said to "roll in" securities borrowed and "roll out" securities when returning the securities to the investor.

As with a repo agreement, it is a collateralized loan that calls for the sale and repurchase of a security. Unlike a repo agreement, the dealer who borrows the securities need not return the identical securities. Specifically, the dealer need only return "substantially identical securities." This means that the security returned by the dealer that borrows the security must match the coupon rate and security type (i.e., issuer and mortgage collateral). This provides flexibility to the dealer. In exchange for this flexibility, the dealer provides 100% financing. That is, there is no overcollateralization or overmargin required. Moreover, the

financing cost may be cheaper than in a repo because of this flexibility. Finally, unlike in a repo, the dealer keeps the coupon and any principal paid during the period of the loan.

Determination of the Financing Cost

Determination of the financing cost is not as simple as in a repo. The key elements in determining the financing cost, assuming that the dealer is borrowing securities/lending cash, are

1. The sale price and the repurchase price
2. The amount of the coupon payment
3. The amount of the principal payments due to scheduled principal payments
4. The projected prepayments of the security sold (i.e., rolled in to the dealer)
5. The attributes of the substantially identical security that is returned (i.e., rolled out by the dealer)
6. The amount of under- or overdelivery permitted

Let's look at these elements. In a repo agreement, the repurchase price is greater than the sale price; the difference represents interest and is called the *drop*. In the case of a dollar roll, the repurchase price need not be greater than the sale price. In fact, in a positively sloped yield-curve environment (i.e., long-term rates exceed short-term rates), the repurchase price will be less than the purchase price. The reason for this is the second element, the coupon payment. The dealer keeps the coupon payment.

The third and fourth elements involve principal repayments—scheduled principal and prepayments. As with the coupon payments, the dealer retains the principal payments during the period of the agreement. A gain will be realized by the dealer on any principal repayments if the security is purchased by the dealer at a discount and a loss if purchased at a premium. Because of prepayments, the principal that will be paid is unknown and, as will be seen, represents a risk in determination of the financing cost.

The fifth element is another risk because the effective financing cost will depend on the attributes of the substantially identical security that the dealer will roll out (i.e., the security it will return to the lender of the securities) at the end of the agreement. Finally, delivery tolerances allowing for a small amount of under- or overdelivery are permitted. In a dollar roll, the investor and the dealer have the option to under- or overdeliver: the investor when delivering the securities at the outset of the transaction and the dealer when returning the securities at the repurchase date. The variance is the amount by which the delivery may deviate from the original trade amount. At one time, the variance permitted could have a

significant impact on the effective financing cost. Today, the impact is minimal because for TBA trades of Ginnie Mae, Fannie Mae, and Freddie Mac pass-throughs, the variance is only ±0.01% of the dollar amount of the original transaction agreed on by the parties. No allowance for variance is permitted for specified pool trades.

To illustrate how the financing cost for a dollar roll is calculated, suppose that an investor enters into an agreement with a dealer in which it agrees to sell \$10 million par value (i.e., unpaid aggregate balance) of Ginnie Mae 8s at $101^{7}/_{32}$ and repurchase substantially identical securities a month later at 101 (the repurchase price). The drop is therefore $^{7}/_{32}$. While under- or overdelivery is permitted, we will assume that \$10 million par value will be delivered to the dealer by the investor and that the same amount of par value will be returned to the investor by the dealer. Since the sale price is $101^{7}/_{32}$, the investor will receive in cash \$10,121,875 (101.21875 × \$10 million). At the repurchase date, the investor can repurchase substantially identical securities for 101, or \$10,100,000. Therefore, the investor can sell the securities for \$10,121,875 and buy them back for \$10,100,000. The difference, which is the drop, is \$21,875.

To offset this, the investor forfeits the coupon interest during the period of the agreement to the dealer. Since the coupon rate is 8%, the coupon interest forfeited is \$66,666 (8% × \$10 million/12). The dealer is also entitled to any principal repayments, both regularly scheduled and prepayments. Since the dealer purchases the securities from the investor at $\$101^{7}/_{32}$, any principal repayments will result in a loss of $\$1^{7}/_{32}$ per \$100 of par value of principal repaid. From the investor's perspective, this is a benefit and effectively reduces the financing cost. While the regularly scheduled amount can be determined, prepayments must be projected based on some Public Securities Association (PSA) speed. In our illustration, for simplicity, let's assume that the regularly scheduled principal payment for the month is \$6,500 and that the prepayment is projected to be \$20,000 based on some PSA speed. Since $\$1^{7}/_{32}$ is lost per \$100 par value repaid, the dealer loses \$79 due to the regularly scheduled principal payment ($1^{7}/_{32}$ × \$6,500/100) and \$244 from prepayments ($1^{7}/_{32}$ × \$20,000/100).

The monthly financing cost is then

Lost coupon interest	\$66,666
Offsets	22,198
Drop (gain from repurchase)	21,875
Principal repayment premium gained	323
Due to regularly scheduled principal	79
Due to prepayments	244
Total financing cost	\$44,468
Monthly financing cost	0.00439
Annual financing cost (monthly rate × 12)	5.27%

The financing cost as calculated, 5.27%, must be compared with alternative financing opportunities. For example, funds can be borrowed via a repo agreement using the same Ginnie Mae collateral. In comparing financing costs, it is important that the dollar amount of the cost be compared with the amount borrowed. For example, in our illustration, we annualized the cost by multiplying the monthly rate by 12. The convention in other financing markets may be different for annualizing.

Risks in a Dollar Roll from the Investor's Perspective

Because of the unusual nature of the dollar roll transaction as a collateralized borrowing vehicle, it is only possible to estimate the financing cost. From our illustration, it can be seen that when the transaction prices are above par value, then the speed of prepayments affects the financing cost. The maximum financing cost can be determined by assuming no prepayments. In this case, the total financing cost would be $244 greater, or $44,712. This increases the monthly financing cost from 5.27% to 5.29%, or 2 basis points. In practice, an investor can perform sensitivity analysis to determine the effect of prepayments on the financing cost.

In addition to the uncertainty about prepayments, the dealer can select the securities to deliver as long as they are substantially identical. However, even among substantially identical securities, there are some pools that perform worse than others. The risk is that the dealer will deliver poorly performing pools.

MARGIN BUYING

Investors can borrow cash to buy securities and use the securities themselves as collateral in a standard margin agreement with a brokerage firm. The funds borrowed to buy the additional securities will be provided by the broker, and the broker gets the money from a bank. The interest rate that banks charge brokers for these transactions is known as the *call money rate* (also called the *broker loan rate*). The broker charges the investor the call money rate plus a service charge.

The broker is not free to lend as much as it wishes to the investor to buy securities. The Securities and Exchange Act of 1934 prohibits brokers from lending more than a specified percentage of the market value of the securities. The initial margin requirement is the proportion of the total market value of the securities that the investor must pay for in cash. The 1934 act gives the Board of Governors of the Federal Reserve the responsibility to *set initial margin requirements*, which it does under Regulations T and U. The initial margin requirement varies for stocks and nongovernment/nonagency bonds and is currently 50%, although it has been below 40%. There are no restrictions on government and government agency securities.

The Fed also establishes a *maintenance margin requirement*. This is the minimum amount of equity needed in the investor's margin account as compared

with the total market value. If the investor's margin account falls below the minimum maintenance margin, the investor is required to put up additional cash. The investor receives a margin call from the broker specifying the additional cash to be put into the investor's margin account. If the investor fails to put up the additional cash, the securities are sold.

SECURITIES LENDING

A security lending transaction involves two parties. The first is the owner of a security who agrees to lend that security to another party. This party is called the *security lender* or the *beneficial owner*. The second party is the entity that agrees to borrow the security, called the *security borrower*. A *security lending transaction* is one in which the security lender loans the requested security to the security borrower at the outset, and the security borrower agrees to return the identical security to the security lender at some time in the future. The loan may be terminated by the security lender on notice to the security borrower, typically of not more than five business days.

To protect against credit risk, the security lender will require that the security borrower provide collateral. Collateral can take the form of (1) cash, (2) a letter of credit, or (3) a security whose value is at least equal in value to the securities loaned. In the United States, the most common form of collateral is cash. Outside the United States, all types of securities have been used as collateral, including common stock and convertible securities. Typically, if the collateral is a security, it is marked-to-market on a daily basis.

When cash is the collateral, the proceeds are reinvested by the security lender. The security lender faces the risks associated with reinvesting the cash. The income generated from reinvesting the cash is given to the security borrower less an amount retained by the security lender for loaning the security because the fee earned by the security lender is then the difference between the income earned from reinvesting the cash and the amount the security lender agrees to pay the security borrower. The security lender's fee is called an *embedded fee* when there is cash collateral. The agreed-on amount that the security lender pays to the security borrower is called a *rebate*. The security lender only earns a fee if the amount earned on reinvesting the cash collateral exceeds the rebate. In fact, if the amount earned is less than the rebate, the security lender incurs this cost.

When the collateral is a letter of credit or a security, the security borrower compensates the security lender by a predetermined fee. This fee is called a *borrow fee*, and it is based on the value of the security borrowed. Notice that while the security lender knows what the fee will be in the case of noncash collateral, this is not the case when there is cash collateral. The fee is a function of the performance of the portfolio or security in which the cash collateral is reinvested.

During the period in which the security is loaned to the borrower, there may be an interest payment (dividend payment in the case of stock). The security

lender is entitled to a payment from the security borrower equal in amount to any such payment. The payment made by the security borrower to the security lender for this purpose is called a *substitute payment* or *in-lieu-of payment*.

A party with a portfolio of securities to lend can either (1) lend directly to counterparties that need securities, (2) use the services of an intermediary, or (3) employ a combination of the first two. If a party decides to lend directly, it must have the in-house capability of assessing counterparty risk. When an intermediary is engaged, the intermediary receives a fee for its services. The intermediary could be an agent (i.e., acts on behalf of a security lender but does not take a principal risk position) or a principal (i.e., takes a principal risk position). Possible agents include the current domestic/global custodian of the securities or a third-party specialist in securities lending.

When cash collateral must be reinvested, a securities lender must decide on whether it will reinvest the cash or use the services of an external money manager. As noted earlier, securities lenders may realize a return on the cash collateral that is less than the rebate.

Comparison to Repurchase Agreements

It is worthwhile to compare a security lending transaction in which the collateral is cash to a repurchase agreement because both transactions represent a secured borrowing. We will do this with an illustration. The parties are as follows:

- Manager X, who is the beneficial owner of security A
- Manager Y, who needs security A to cover a short position

Also suppose that security A is a debt instrument that pays coupon interest.

The following agreement is entered into by manager X and manager Y:

1. Manager X agrees to transfer security A to manager Y.
2. Manager Y agrees to give cash to manager X.
3. At some future date, manager Y agrees to return security A to manager X.
4. Manager X agrees to return the cash to manager Y when manager Y returns security A to manager X.

The economics of this transaction are simple: it is a secured loan of cash with the lender of cash being manager Y and the borrower of cash being manager X. The collateral for this loan is security A. This transaction can be structured as a security lending or a repurchase agreement. No matter what it is called, the economics are unchanged.

If this transaction is structured as a security lending agreement, then

1. Manager X is the security lender (beneficial owner).
2. Manager Y is the security borrower.

3. Manager X invests the cash received from manager Y and at the end of the transaction rebates part of the income earned to manager Y.
4. The amount earned by manager X from security lending is uncertain and, in fact, can be negative.
5. Manager Y pays manager X any interest income that manager X would have received from the issuer of the security.
6. At some future time, manager X requests the return of security A and returns the cash collateral to manager Y.

If this transaction is structured as a repurchase agreement, then

1. Manager X is the seller of collateral or, equivalently, the borrower of funds using security A as collateral.
2. Manager Y is the buyer of collateral or, equivalently, the lender of funds.
3. Manager X invests the cash received from manager Y and at the repurchase date pays interest to manager Y based on the repo rate.
4. The amount earned by manager X from the repurchase agreement is uncertain and, in fact, can be negative.
5. Manager Y pays manager X any interest income that manager X would have received from the issuer of the security.
6. At the repurchase date, manager X buys back security A from manager Y at the repurchase price (which includes interest).

Whether the transaction is a repo or reverse repo depends on the perspective of the parties, as discussed earlier in this chapter. Notice that unlike a repurchase agreement, which has a repurchase date—which can be rolled over—there is no repurchase price in a security lending transaction.

KEY POINTS

- A repurchase agreement is the sale of a security with a commitment by the seller to buy the security back from the purchaser at a specified price on a designated future date.
- Repo margin or haircut is the amount by which the security's value exceeds the loan amount.
- A dollar roll is a specialized type of collateralized loan particular to the MBS market.
- Investors can borrow cash to buy securities and use the securities themselves as collateral with a standard margin agreement with a brokerage firm.

- A securities lending transaction involves one party lending a security and accepting collateral while another party borrows a security and provides collateral.
- In order to induce the security borrower to provide cash as collateral as opposed to some other form (e.g., another security or letter of credit), the security lender pays the security borrower a prespecified fee called the rebate rate.

With the advent of options, futures, and forwards on interest-rate instruments, proactive fixed income risk management, in its broadest sense, assumes a new dimension. Investment managers and traders can achieve new degrees of freedom. It is now possible to alter the interest-rate sensitivity of a fixed income portfolio economically and quickly. *Derivative contracts,* known as such because they derive their value from an underlying instrument, offer investment managers and traders risk and return patterns that were previously either unavailable or too costly. Futures contracts can be used to control risk exposure with hedging being a special case of eliminating risk. In addition, futures contracts can be used to build synthetic positions in the underlying assets.

The purpose of this chapter is twofold. First, we explain the basic characteristics of options, futures, and forward contracts. Second, we review the most actively traded and most representative over-the-counter (OTC) and listed contracts. We omit from our discussion the use of futures for controlling interest rate risk; this topic will be explained in more detail in Chapter 61.

BASIC CHARACTERISTICS OF DERIVATIVE CONTRACTS

Futures Contracts

A *futures contract* is an agreement between a buyer (seller) and an established futures exchange or its clearinghouse in which the buyer (seller) agrees to take (make) delivery of a specific amount of a valued item such as a commodity, stock, or bond at a specified price during a designated time. For some futures contracts, settlement at expiration is in cash rather than actual delivery.

When an investor takes a position in the market by buying a futures contract, the investor is said to be *long the futures* or have a *long position in the futures.* If, instead, the investor's opening position is the sale of a futures contract, the investor is said to be *short the futures* or have a *short position in the futures.*

Futures contracts based on a financial instrument or a financial index are known as *financial futures.* Financial futures can be classified as interest-rate futures, stock index futures, or currency futures. This chapter focuses on interest-rate futures and includes a description of the most important interest-rate futures contracts currently traded.

To illustrate how financial futures work, suppose that *X* buys a futures contract and *Y* sells a futures contract on a 6% five-year Treasury note for settlement one year from now. Suppose also that the price at which *X* and *Y* agree to transact one year from now is $100. This is the futures price. This means that one year from now *Y* must deliver a 6% five-year Treasury note and will receive $100. *X* will take delivery of a 6% five-year Treasury note and will pay $100.

The profit or loss realized by the buyer or seller of a futures contract depends on the price and interest rate on the delivery date. For example, if the market price of a 6% five-year Treasury note at the settlement date is $110, because rates have declined, the buyer profits, paying $100 for a security that is worth $110. In contrast, the seller loses, because an instrument worth $110 must be delivered in exchange for $100. If interest rates rise on 6% five-year Treasury notes so that the market price is $90, the seller of the futures contract profits and the buyer loses.

When the investor first takes a position in a futures contract, he must deposit a minimum dollar amount per contract as specified by the exchange. As the price of the futures contract fluctuates, the value of the investor's equity in the position changes. At the close of each trading day, any market gain results in an increase in the investor's equity, whereas any market loss results in a decrease. This process is referred to as *marking to market.* Should an investor's equity position fall below an amount determined by the exchange, he must provide additional margin. On the other hand, if an investor's equity increases, he may withdraw funds. Consequently, a futures position may require substantial cash-flows before the delivery date. Margin is described in more detail later in this chapter.

Forward Contracts

A *forward contract* is much like a futures contract. A forward contract is an agreement for the future delivery of some amount of a valued item at a specified price at a designated time. Futures contracts are standardized agreements that define the delivery date (or month) and quality and quantity of the deliverable. Futures contracts are traded on organized exchanges. A forward contract is, in contrast, usually nonstandardized and is traded over the counter by direct contact between buyer and seller.

Although both futures and forward contracts set forth terms of delivery, futures contracts are not intended to be settled by delivery. In fact, generally only a small percentage of outstanding futures contracts are delivered or go to final settlement. However, forward contracts *are* intended to be held to final settlement. Many of the most popular forward contracts, however, settle in cash rather than actual delivery.

Forward contracts may or may not be marked to market. Consequently, there is no interim cash-flow on forwards that are not marked to market.

Finally, both parties in a forward contract are exposed to credit risk because either party may default on its obligation. In contrast, credit risk for futures contracts is minimal because the clearing corporation associated with the exchange guarantees the other side of each transaction.

Options

An *option* is a contract in which the seller of the option grants the buyer of the option the right to purchase from, or sell to, the contract seller a designated instrument at a specified price within a specified period of time. The seller (or *writer*) grants this right to the buyer in exchange for a certain sum of money, called the *option price* or *option premium.*

The price at which the instrument may be bought or sold is called the *exercise* or *strike price.* The date after which an option is void is called the *expiration date.* An *American option* may be exercised any time up to and including the expiration date. A *European option* may be exercised only on the expiration date.

When an option writer grants the buyer the right to purchase the designated instrument, it is called a *call option.* When the option buyer has the right to sell the designated instrument to the writer, the option is called a *put option.* The buyer of an option is said to be *long the option;* the writer is said to be *short the option.*

Consider, for example, an option on a 6% five-year Treasury note with one year to expiration and an exercise price of $100. Suppose that the option price is $2 and the current price of the Treasury note is $100 with a yield of 6%. If the option is a call option, then the buyer of the option has the right to purchase a 6% five-year Treasury note for $100 within one year. The writer of the option must sell the Treasury note for $100 to the buyer if he or she exercises the option. Suppose that the interest rate on the Treasury note declines and its price rises to $110. By exercising the call option, the buyer realizes a profit, paying $100 for

a Treasury note that is worth $110. After considering the cost of buying the option, $2, the net profit is $8. The writer of the option loses $8. If, instead, the market interest rate rises and the price of the Treasury note falls below $100, the call option buyer will not exercise the option, losing the option price of $2. The writer will realize a profit of $2. Thus the buyer of a call option benefits from a decline in interest rates (a rise in the price of the underlying fixed income instrument) and the writer loses.

If the option is a put rather than a call and the interest rate on Treasury notes declines and the price rises above $100, the option buyer will not exercise the option. The buyer will lose the entire option price. If, on the other hand, the interest rate on Treasury notes rises and the note's price falls below $100, the option buyer will profit by exercising the put option. In the case of a put option, the option buyer benefits from a rise in interest rates (a decline in the price of the underlying fixed income instrument) and the option seller loses.

The maximum amount that an option buyer can lose is the option price. The maximum profit that the option writer (seller) can realize is the option price. The option buyer has substantial potential upside return, whereas the option writer has substantial downside risk. The risk/reward relationships for option positions are investigated in Chapter 64.

Options can be written on cash instruments or futures. The latter are called *futures options* and are traded only on exchanges. Options on cash instruments are also traded on exchanges but have been traded much more successfully over the counter. These *OTC,* or *dealer, options* are tailor-made options on specific Treasury issues, mortgage securities, or interest-rate indexes. Option contracts are reviewed later in this chapter.

Differences between Option and Futures (or Forward) Contracts

Unlike a futures or forward contract, an option gives the buyer the *right* but not the *obligation* to perform. The option seller has the obligation to perform. In the case of a futures or forward contact, both the buyer and seller are obligated to perform. In addition, the buyer of a futures or forward contract does not pay the seller to accept the obligation, whereas in the case of an option, the buyer pays the seller an option premium.

Consequently, the risk/reward characteristics of the two contracts also differ. In a futures or forward contract, the long position realizes a dollar-for-dollar gain when the price of the futures or forward increases and suffers a dollar-for-dollar loss when the price of the futures or forward decreases. The opposite holds for a short position. Options do not provide such a symmetric risk/reward relationship. The most a long position may lose is the option premium, yet the long retains all the upside potential. However, the gain is always reduced by the price of the option. The maximum profit the short position may realize is the option price, but the short position has substantial downside risk.

REPRESENTATIVE EXCHANGE-TRADED INTEREST-RATE FUTURES CONTRACTS

Interest-rate futures contracts can be classified by the maturity of their underlying security. Short-term interest-rate futures contracts have an underlying security that matures in less than one year or a short-term reference interest rate. The maturity of the underlying security of long-term futures exceed one year. Exhibit 59-1 displays most interest rate futures contracts traded in the United States. The contracts are arranged along the yield-curve from short-term interest rates through the Ultra Long Bond contract. Notice that some of the contracts have physical settlement. Other contracts are cash settled. The success of cash settled contracts depends on having the price or yield in the calculation not be subject to manipulation. Below we describe the specifications of the long-term futures contracts (Treasury bond futures and Treasury notes futures) and short-term futures contracts (Treasury bill futures, Eurodollar futures, interest-rate swap futures, and federal funds futures).

The Treasury Bond Futures Contract

The Treasury bond (T-bond) futures contract is the most successful interest-rate (or commodity) futures contract. Prices and yields on the T-bond futures contract are quoted in terms of a (fictitious) 20-year 6% Treasury bond, but the exchange where the contract is traded, the Chicago Mercantile Exchange (CME), allows many different bonds to be delivered in satisfaction of a short position in the contract. Specifically, any Treasury bond with a remaining maturity of at least 15 years, but less than 25 years, from the first day of the delivery month is acceptable for delivery. There is an Ultra Long Treasury futures contract that differs only in that it is based on Treasury bonds with at least 25 years to maturity.

The T-bond futures contract calls for the short (i.e., the seller) to deliver $100,000 face value of any one of the qualifying Treasury bonds. However, because the coupons and maturities vary widely, the price that the buyer pays the seller depends on which bond the seller chooses to deliver. The rule used by the CME is one that adjusts the futures price by a conversion factor that reflects the price the bond would sell for at the beginning of the delivery month if it were yielding 6%. Using such a rule, the conversion factor for a given bond and a given delivery month is constant through time and is not affected by changes in the price of the bond or the price of the futures contract.

The seller has the right to choose which qualifying bond to deliver and when during the delivery month delivery will take place. When the bond is delivered, the buyer is obligated to pay the seller the futures price multiplied by the appropriate conversion factor, plus accrued interest on the delivered bond. It is important to emphasize that while the underlying Treasury bond for this contract is a hypothetical issue and therefore cannot itself be delivered into the futures

EXHIBIT 59–1

Representative Exchange-Traded Interest-Rate Futures Contracts

Contract	Form	Contract Size	Contract Months	Settlement
Eurodollar 1-month	Futures	$3,000,000	First 12 consecutive calendar months.	Cash
Fed Funds 30-day	Futures	$5,000,000	First 24 Calendar Months	Cash
Eurodollar 3-month	Futures	$1,000,000	Mar/Jun/Sep/Dec 40 contracts = 10 years	Cash
Overnight Index Swap 3-months	Futures	$1,000,000	First eight months in the March quarterly cycle (i.e., White and Red expiry years)	Cash
Treasury 2-year	Futures	$200,000	The first five consecutive contracts in the March, June, September, and December quarterly cycle	Physical
OTR 2-year	Futures	$100,000	Corresponds to 2-year Treasury notes auctions. Final Settlement Date is the morning of the following new Treasury note auction (in the named expiry month).	Cash
Treasury 3-year	Futures	$200,000	The first five consecutive contracts in the March, June, September, and December quarterly cycle	Physical
Treasury 5-year	Futures	$100,000	The first five consecutive contracts in the March, June, September, and December quarterly cycle	Physical
OTR 5-year	Futures	$100,000	Corresponds to 5-year Treasury notes auctions. Final Settlement Date is the morning of the following new Treasury note auction (in the named expiry month).	Cash

EXHIBIT 59–1

Representative Exchange-Traded Interest-Rate Futures Contracts (*Continued*)

Contract	Form	Contract Size	Contract Months	Settlement
Swap 5-year	Futures	$100,000	The first three consecutive contracts in the March, June, September, and December quarterly cycle.	Cash
Swap 7-year	Futures	$100,000	The first three consecutive contracts in the March, June, September, and December quarterly cycle.	Cash
Treasury 10-year	Futures	$100,000	The first five consecutive contracts in the March, June, September, and December quarterly cycle	Physical
OTR 10-year	Futures	$100,000	Corresponds to 10-year Treasury notes auctions. Final Settlement Date is the morning of the following new Treasury note auction (in the named expiry month).	Cash
Swap 10-year	Futures	$100,000	The first three consecutive contracts in the March, June, September, and December quarterly cycle.	Cash
Treasury Bond	Futures	$100,000	The first five consecutive contracts in the March, June, September, and December quarterly cycle	Physical/ Maturity at last 15 years from first day of delivery month, but less than 25 years, from first day of delivery month.
Treasury Ultra Bond	Futures	$100,000	The first five consecutive contracts in the March, June, September, and December quarterly cycle	Physical/ Remaining maturity of not less that 25 years from the first day of delivery month
Swap 30-year	Futures	$100,000	The first three consecutive contracts in the March, June, September, and December quarterly cycle.	Cash
Barclay's U.S. Index	Futures	$100 × Index Value of Barclays Capital Aggregate Bond Index.	March, June, September, and December (March quarterly cycle)	Cash

contract, the bond futures contract is not a cash settlement contract. To close out a Treasury bond futures contract, one can either initiate an offsetting futures position or deliver a qualifying issue.

Paradoxically, the success of the CME Treasury bond contract can in part be attributed to the fact that the delivery mechanism is not as simple as it may first appear. There are several options implicit in a position in bond futures. First, the seller chooses which bond to deliver. Thus, the seller has an option to swap between bonds. If the seller is holding bond A for delivery, but bond B becomes cheaper to deliver, she can swap bond B for bond A and make a more profitable delivery. Second, within some guidelines set by the CME, the seller decides when during the delivery month delivery will take place. She thus has a timing option that can be used to her advantage. Finally, the short retains the possibility of making the wildcard play. This potentially profitable situation arises from the fact that the seller can give notice of intent to deliver for several hours after the exchange has closed and the futures settlement price has been fixed. In a falling market, the seller can use the wildcard option to profit from the fixed delivery price.

The seller's options tend to make a contract a bit more difficult to understand, but at the same time they make the contract more attractive to speculators, arbitrageurs, dealers, and anyone else who understands the contract better than other market participants. Thus, in the case of the Treasury bond futures contract, complexity has helped provide liquidity.

Treasury Note Futures

There are three Treasury note futures contracts: 10-year, 5-year, and 2-year. All three contracts are modeled after the Treasury bond futures contract and are traded on the CME. The underlying instrument for the 10-year Treasury note futures contract is $100,000 par value of a hypothetical 10-year 6% Treasury note. There are several acceptable Treasury issues that may be delivered by the short. A note is acceptable if the maturity is not less than 6.5 years and not greater than 10 years from the first day of the delivery month. The delivery options granted to the short position are the same as for the Treasury bond futures contract.

For the 5-year Treasury note futures contract, the underlying is $100,000 par value of a U.S. Treasury note that satisfies the following conditions: an original maturity of not more than five years and three months and a remaining maturity of not less than four years and two months as of the first day of the delivery month.

The underlying for the 2-year Treasury note futures contract is $200,000 par value of a U.S. Treasury note with a remaining maturity of not more than two years and not less than one year and nine months. Moreover, the original maturity of the note delivered to satisfy the two-year futures cannot be more than five years and three months.

Treasury Bill Futures Contract

The IMM's futures contract on Treasury bills was the first contract on a short-term debt instrument, and has been the model for most subsequent contracts on short-term debt. The contract is based on three-month Treasury bills with a face value of $1 million. As of the third quarter of 2011, there was very little open interest in this contract.

The contract is quoted and traded in terms of a futures "price," but the futures price is, in fact, just a different way of quoting the futures interest rate. Specifically, the futures price is the annualized futures rate subtracted from 100. For example, a futures price of 97.50 means that Treasury bills are trading in the futures market at a rate of 2.50%. The actual price that the buyer pays the seller is calculated using the usual formula for Treasury bills:

$$\text{Invoice price} = \$1{,}000{,}000 \times \left[1 - \text{rate} \times \left(\frac{\text{days to maturity}}{360}\right)\right]$$

where the rate is expressed in decimal form. As this formula shows, each basis point change in the interest rate (or each 0.01 change in the futures price) leads to a $25 change in the invoice price for a 90-day bill. Consequently, the value of a 0.01 change in the futures contract is always $25.

The Treasury bill futures contract is considerably simpler than the T-bond and T-note futures contracts. First, because all Treasury bills of the same maturity are economically equivalent, there is effectively only one deliverable issue, namely, Treasury bills with three months to maturity. Three months may have 90, 91 or 92 days depending on the month in which the contract is initiated. The fact that the three-month bills may be either new three-month bills or older bills that currently have three months of remaining life makes little difference because the new and old issues will trade the same in the cash market. Thus, all the subtleties surrounding conversion factors and most deliverable issues are absent from the Treasury bill futures market. Furthermore, there is little uncertainty or choice involved in the delivery date, because delivery must take place during a very narrow time frame, usually a three-day period. The rules of the exchange make clear well in advance the exact dates on which delivery will take place. Finally, because there are no conversion factors, there is no wildcard play in the Treasury bill futures market.

Although the Treasury bill futures contract is simple and thus may not provide as many speculative and arbitrage opportunities as the more complex long- and intermediate-term futures contracts, it does provide a straightforward means of hedging or speculating on the short end of the yield-curve. Because the Treasury bill rate is a benchmark off which other short-term rates may be priced, the bill contract fills a well-defined need of many market participants.

Eurodollar Futures Contract

Eurodollar CDs are U.S. dollar-denominated CDs issued primarily in London by U.S., Canadian, European, and Japanese banks. These CDs earn a fixed-rate of

interest related to dollar LIBOR. The term LIBOR comes from the London Interbank Offered Rate and is the interest rate at which one London bank offers funds to another London bank of acceptable credit quality in the form of a cash deposit. The rate is "fixed" by the British Bankers Association every business morning by the average of the rates supplied by member banks.

Three-month LIBOR is the underlying instrument for the Eurodollar futures contract. The contracts are traded on the International Monetary Market of the CME and the Eurex International Financial Futures Exchange (LIFFE). This contract has a $1 million face value and is traded on an index price basis. The index price basis in which the contract is quoted is equal to 100 minus the annualized futures LIBOR. For example, a Eurodollar futures price of 97.50 means a futures 3-month LIBOR of 2.50%.

The minimum price fluctuation or tick for this contract is 0.005 or 1/2 basis point. Accordingly, the tick value for this contract is $12.50 as determined by the following expression:

$$\text{Tick value} = \$1{,}000{,}000 \times (0.005 \times 90/360) = \$12.50$$

The Eurodollar futures contract is a cash settlement contract. There are Eurodollar futures contracts available to trade with quarterly expiration dates (March, June, September, and December) that extend out 10 years. Accordingly, it is possible for market participants to hedge or speculate on the level of three-month LIBOR for the next decade.

The Eurodollar futures contract is used frequently to trade the short end of the yield-curve and many hedgers believe this is the ideal contract for a wide range of hedging situations. Moreover, the Eurodollar futures market and interest rate swaps are intensely interconnected. When valuing swaps at their inception, the future path of floating rates are derived from positions in Eurodollar futures contracts.

The 90-day sterling LIBOR interest rate futures contract trades on the main London Futures Exchange, LIFFE. The contract is structured similarly to the Eurodollar futures contract described above. Prices are quoted as 100 minus the interest rate and the expiration months are March, June, September, and December. The contract size is £500,000. A tick is 0.01 or one basis point and the tick value is £12.5.

The LIFFE also trades short-term interest rate futures for other major currencies including euros, yen, and Swiss francs. Short-term interest rate futures contracts in other currencies are similar to the 90-day sterling LIBOR contract and trade on exchanges such as Deutsche Terminbourse in Frankfurt and MATIF (Marché à Terme International de France) in Paris.

Swap Futures Contracts

Interest-rate swaps are discussed in Chapter 62. The CME introduced a swap futures contract in 2001. The underlying instrument is the notional price of the fixed-rate side of a 10-year interest-rate swap that has a notional principal equal

to $100,000 and that exchanges semiannual interest payments at a fixed annual rate of 6% for floating interest-rate payments based on three-month LIBOR.

This swap futures contract is cash-settled, with a settlement price determined by the International Swap and Derivatives Association (ISDA) benchmark 10-year swap rate on the last day of trading before the contract expires. This benchmark rate is published with a one-day lag in the Federal Reserve Board's statistical release H.15. Contracts have settlement months of March, June, September, and December, just like the other CME interest-rate futures contracts that we have discussed.

The London International Financial Futures Exchange (LIFFE) introduced the first swap futures contract called Swapnote, which is referenced to the euro interest-rate swap curve. Swapnotes are available in 2-, 5-, and 10-year maturities.

Fed Funds Futures Contracts

The 30-day federal funds futures contract is designed for financial institutions and businesses who want to control their exposure to movements in the federal funds rate. These contracts have a notional amount of $5 million, and the contract can be written for the current month up to 24 months in the future. Underlying this contract is the simple average overnight federal funds rate (i.e., the effective rate) for the delivery month. As such, this contract is settled in cash on the last business day of the month. Just as the other short-term interest-rate futures contracts discussed earlier, prices are quoted on the basis of 100 minus the overnight federal funds rate for the delivery month. These contracts are marked to market using the effective daily federal funds rate as reported by the Federal Reserve Bank of New York.

Other Futures Contracts

If the yield-curve were flat and moved in parallel shifts, a single futures contract would be sufficient for all fixed income hedging and speculative purposes. Different note or bond positions would differ only in the number of contracts needed for a hedge. For example, with perfectly correlated interest rate changes, one could hedge long bonds with Treasury bill futures. It would require many multiples of the bond's par value in Treasury bills futures for the hedge, but it would work perfectly. The only challenge would be to get the scale of the hedges right.

Historically, the yield-curve shifts parallel to itself, steepens or flattens, and becomes more or less curved. Consequently, multiple kinds of contracts are needed to hedge bonds of varying maturity. In addition, because credit-spreads widen and narrow, at least one contract with credit risk embedded is needed to allow complete hedging.

The on-the-run (OTR) U.S. Treasury futures contracts are based on prices derived from the yields of on-the-run (most recently auctioned) 2-year, 5-year, and 10-year Treasury notes. These contracts are designed to give users synthetic exposure to the most liquid benchmark maturities on the U.S. Treasury yield curve.

Unlike traditional Treasury futures, OTR Treasury futures have cash settlement. The notional underlying is a U.S. Treasury note with a face value of $100,000 paying a 4% coupon rate per annum on a semiannual basis.

As noted above, credit-spreads widen and narrow and are not perfectly correlated to shifts in the yield-curve. This fact suggests there should be a futures contract derived from bonds with exposure to credit risk. Consider the Barclays Capital U.S. Aggregate Bond Index futures contract that trades on the CME. The underlying instrument is the index value multiplied by $100. The index includes all of the sectors of the bond market: Treasury, agency, corporate, agency mortgage-backed, asset-backed, and commercial mortgage-backed.

MECHANICS OF FUTURES TRADING

Types of Orders

When a trader wants to buy or sell a futures contract, the price and conditions under which the order is to be executed must be communicated to a futures broker. The simplest type of order, yet potentially the most perilous from the trader's perspective, is the *market order.* When a market order is placed, it is executed at the best price available as soon as the order reaches the trading pit, the area on the floor of a futures exchange where all transactions for a specific contract are made. The danger of market orders is that an adverse move may take place between the time the trader places the order and the time the order reaches the trading pit.

To avoid the dangers associated with market orders, the trader can place a *limit order* (or *resting order*) that designates a price limit for the execution of the transaction. A *buy limit order* indicates that the futures contract may be purchased only at the designated price or lower. A *sell limit order* indicates that the futures contract may be sold only at the designated price or higher.

The danger of a limit order is that there is no guarantee that it will be executed at all. The designated price may simply not be obtainable. Even if the contract trades at the specified price, the order may not be filled because the market does not trade long enough at the specified price (or better) to fill all outstanding orders. Nevertheless, a limit order may be less risky than a market order. The trader has more control with a limit order, because the price designated in the limit order can be revised based on prevailing market prices as long as the order has not already been filled.

The limit order is a conditional order: It is executed only if the limit price or a better price can be obtained. Another type of conditional order is the *stop order.* A stop order specifies that the order is not to be executed until the market reaches a designated price, at which time it becomes a market order. A *buy stop order* specifies that the order is not to be executed until the market rises to a designated price (i.e., trades at or above, or is bid at or above, the designated price). A *sell stop order* specifies that the order is not to be executed until the market price falls below a designated price (i.e., trades at or below, or is offered at or below, the designated price). A stop order is useful when a futures trader already has a position on but

cannot watch the market constantly. Traders can preserve profits or minimize losses on open positions by allowing market movements to trigger a closing trade. In a sell (buy) stop order, the designated price is less (greater) than the current market price of the futures contract. In a sell (buy) limit order the designated price is greater (less) than the current market price of the futures contract.

There are two dangers associated with stop orders. Because futures markets sometimes exhibit abrupt price changes, the direction of the change in the futures price may be very temporary, resulting in the premature closing of a position. Also, once the designated price is reached, the stop order becomes a market order and is subject to the uncertainty of the execution price noted earlier for market orders.

A *stop-limit order,* a hybrid of a stop order and a limit order, is a stop order that designates a price limit. Thus, in contrast to the stop order, which becomes a market order if the stop is reached, the stop-limit order becomes a limit order if the stop is reached. The order can be used to cushion the market impact of a stop order. The trader may limit the possible execution price after the activation of a stop. As with a limit order, the limit price might never be reached after the order is activated, and therefore the order might not be executed. This, of course, defeats one purpose of the stop order—to protect a profit or limit a loss.

A trader also may enter a *market-if-touched order.* A market-if-touched is like a stop order in that it becomes a market order if a designated price is reached. However, a market-if-touched order to buy would become a market order if the market *falls* to a given price, whereas a stop order to buy becomes a market order if the market *rises* to a given price. Similarly, a market-if-touched order to sell becomes a market order if the market rises to a specified price, whereas the stop order to sell becomes a market order if the market falls to a given price. One may think of the stop order as an order designed to exit an existing position at an acceptable price (without specifying the exact price), and the market-if-touched order as an order designed to enter a position at an acceptable price (also without specifying the exact price).

Orders may be placed to buy or sell at the open or the close of trading for the day. An *opening order* indicates that a trade is to be executed only in the opening range for the day, and a *closing order* indicates that the trade is to be executed only within the closing range for the day.

Futures brokers may be allowed to try to get the best possible price for their clients. The *discretionary order* gives the broker a specified price range in which to fill the order. For example, a discretionary order might be a limit order that gives the broker a one-tick (i.e., one basis point or $^1/_{32}$) discretion to try to do better than the limit price. Thus, even if the limit price is reached and the order could be filled at that limit, the broker can wait for a better price. However, if it turns out that the market goes in the wrong direction, the broker must fill the order but at no worse than one tick from the limit price. A *not held order* gives the broker virtually full discretion over the order. The not held order may be placed as any of the orders mentioned so far (market, stop, limit, etc.), but if the broker believes that filling the orders is not advisable, he or she need not fill them.

A client may enter orders that contain order cancellation provisions. A *fill-or-kill* order must be executed as soon as it reaches the trading floor, or it is canceled immediately. A *one-cancels-other order* is a pair of orders that are worked simultaneously, but as soon as one order is filled, the other is canceled automatically.

Orders may designate the time period for which the order is effective—a day, week, or month, or perhaps by a given time within the day. An *open order,* or *good-til-canceled order* is good until the order is specifically canceled. If the time period is not specified, it is usually assumed to be good only until the end of the day. For some orders, like the market order, a specific time period is not relevant, because they are executed immediately.

On execution of an order, the futures broker is required to provide confirmation of the trade. The confirmation indicates all the essential information about the trade. When the order involves the liquidation of a position, the confirmation shows the profit or loss on the position and the commission costs.

Taking and Liquidating a Position

Once an account has been opened with a broker, the futures trader may take a position in the market. If the trader buys a futures contract, she is said to have a long position. If the trader's opening position is the sale of the futures contract, she is said to have a short position.

The futures trader has two ways to liquidate a position. To liquidate a position before the delivery date, she must take an offsetting position in the same contract. For a long position, this means selling an identical number of contracts; for a short position, this means buying an identical number of contracts.

The alternative is to wait until the delivery date. At that time, the investor liquidates a long position by accepting the delivery of the underlying instrument at the agreed-on price or liquidates a short position by delivering the instrument at the agreed-on price. For interest-rate futures contracts that do not call for actual delivery (e.g., Eurodollar futures), settlement is in cash at the settlement price on the delivery date.

The Role of the Clearing Corporation

When an investor takes a position in the futures market, there is always another party taking the opposite position and agreeing to satisfy the terms set forth in the contract. Because of the *clearing corporation* associated with each exchange, the investor need not worry about the financial strength and integrity of the party taking the opposite side of the contract. After an order is executed, the relationship between the two parties is severed. The clearing corporation interposes itself as the buyer for every sale and the seller for every purchase. Thus the investor is free to liquidate a position without involving the other party to the original transaction and without worry that the other party may default. However, the investor *is* exposed to default on the part of the futures broker through which the trade is placed. Thus, each institution should make sure that the futures broker (and specifically the *subsidiary* that trades futures) has adequate capital to ensure that there is little danger of default.

Margin Requirements

When first taking a position in a futures contract, an investor must deposit a minimum dollar amount per contract as specified by the exchange. (A broker may ask for more than the exchange minimum, but may not require less than the exchange minimum.) This amount is called the *initial margin,* and constitutes a good faith deposit. The initial margin may be in the form of Treasury bills. As the price of the futures contract fluctuates, the value of equity in the position changes. At the close of each trading day, the position is marked to market, so that any gain or loss from the position is reflected in the equity of the account. The price used to mark the position to market is the settlement price for the day.

Maintenance margin is the minimum level to which an equity position may fall as a result of an unfavorable price movement before additional margin is required. The additional margin deposited, also called *variation margin,* is simply the amount that will bring the equity in the account back to its initial margin level. Unlike original margin, variation margin must be in cash. If there is excess margin in the account, that amount may be withdrawn.[1]

If a variation margin is required, the party is contacted by the brokerage firm and informed of the additional amount that must be deposited. A margin notice is sent as well. Even if futures prices subsequently move in favor of the institution such that the equity increases above the maintenance margin, the variation margin must still be supplied. Failure to meet a request for variation margin within a reasonable time will result in the closing out of a position.

Margin requirements vary by futures contract and by the type of transaction; that is, whether the position is an outright long or short or a spread (a long together with a short), and whether the trade is put on as a speculative position or as a hedge. Margins are higher for speculative positions than for hedging positions and higher for outright positions than for spreads. Margin requirements also vary between futures brokers. Exchanges and brokerage firms change their margin requirements as contracts are deemed to be more or less risky, or as it is felt that certain types of positions (usually speculative positions) should be discouraged.

REPRESENTATIVE EXCHANGE-TRADED FUTURES OPTIONS CONTRACTS

Although futures contracts are relatively straightforward financial instruments, options on futures (or *futures options,* as they are commonly called) deserve extra explanation. Options on futures are very similar to other options contracts.

1. Although there are initial and maintenance margin requirements for buying stocks and bonds on margin, the concept of margin differs for futures. When securities are bought on margin, the difference between the price of the security and the initial margin is borrowed from the broker. The security purchased serves as collateral for the loan and interest is paid by the investor. For futures contracts, the initial margin, in effect, serves as good-faith money, indicating that the investor will satisfy the obligation of the contract. No money is borrowed by the purchaser. Similarly, the seller of futures borrows neither money nor securities.

Like options on cash (or spot) fixed income securities, both put and call options are traded on fixed income futures. The buyer of a call has the right to buy the underlying futures contract at a specific price. The buyer of a put has the right to sell the underlying futures contract at a specific price. If the buyer chooses to exercise the option, the option seller is obligated to sell the futures in the case of the call, or buy the futures in the case of the put.

An option on the futures contract differs from more traditional options in only one essential way: The underlying instrument is not a spot security, but a futures contract on a security. Thus, for instance, if a call option buyer exercises her option, she acquires a long position in futures instead of a long position in a cash security. The seller of the call will be assigned the corresponding short position in the same futures contract. For put options the situation is reversed. A put option buyer exercising the option acquires a short position in futures, and the seller of the put is assigned a long position in the same futures contract. The resulting long and short futures positions are like any other futures positions and are subject to daily marking to market.

An investor acquiring a position in futures does so at the current futures price. However, if the strike price on the option does not equal the futures price at the time of exercise, the option seller must compensate the option buyer for the discrepancy. Thus, when a call option is exercised, the seller of the call must pay the buyer of the call the current futures price minus the strike price. On the other hand, the seller of the put must pay the buyer of the put the strike price minus the current futures price. (These transactions are actually accomplished by establishing the futures positions at the strike price, then immediately marking to market.) Note that, unlike options on spot securities, the amount of money that changes hands at exercise is only the difference between the strike price and the current futures price, not the whole strike price. Of course, an option need not be exercised for the owner to take her gains; she can simply sell the option instead of exercising it.

We now turn to the options contracts themselves. We describe two of the most important contracts, the CME's options on the long-term bond futures contract and on the Eurodollar contract. There are also options on the 5- and 10-year note futures contracts, but because they are both very similar in structure to options on Treasury bond futures, they are not included in this section.

Options on Treasury Bond Futures

Options on CME Treasury bond futures are in many respects simpler than the underlying futures contracts. Usually, conversion factors, most deliverables, wildcard plays, and other subtleties of the Treasury bond futures contract need not concern the buyer or seller of options on Treasury bond futures. Although these factors affect the fair price of the futures contract, their impact is already reflected in the futures price. Consequently, they need not be reconsidered when buying or selling an option on the futures.

The option on the Treasury bond futures contract is in many respects an option on an index; the "index" is the futures price itself, that is, the price of the fictitious 20-year 6% Treasury bond. As for the futures contract, the nominal size of the contract is $100,000. Thus, for example, with futures prices at 95, a call option struck at 94 has an intrinsic value of $1,000 and a put struck at 100 has an intrinsic value of $5,000.

In an attempt to compete with the OTC option market, *flexible Treasury futures options* were introduced. These futures options allow counterparties to customize options within certain limits. Specifically, the strike price, expiration date, and type of exercise (American or European) can be customized subject to CME constraints. One key constraint is that the expiration date of a flexible contract cannot exceed that of the longest standard option traded on the CME. Unlike an OTC option, where the option buyer is exposed to counterparty risk, a flexible Treasury futures option is guaranteed by the clearinghouse. The minimum size requirement for the launching of a flexible futures option is 100 contracts.

The premiums for options on Treasury bond futures are quoted in terms of points and 64ths of a point. Thus an option premium of 1-10 implies a price of $1\,{}^{10}/_{64}\%$ of face value, or $1,156.25 (from $100,000 × 1.15625%). Minimum price fluctuations are also ${}^{1}/_{64}$ of 1%.

Although an option on the Treasury bond futures contract is hardly identical to an option on a Treasury bond, it serves much the same purpose. Because spot and futures prices for Treasury bonds are highly correlated, hedgers and speculators frequently find that options on bond futures provide the essential characteristics needed in an options contract on a long-term fixed income instrument.

Options on Eurodollar Futures

Options on Eurodollar futures fill a unique place among exchange-traded hedging products. These options are currently the only liquid listed option contracts based on a short-term interest rate.

Options on Eurodollar futures (traded on the CME) are based on the quoted Eurodollar futures price (i.e., 100 minus the annualized yield). Like the underlying futures, the size of the contract is $1 million and each 0.01 change in price carries a value of $25. Likewise, the option premium is quoted in terms of basis points. Thus, for example, an option premium quoted as 20 (or 0.20) implies an option price of $500; a premium of 125 or (1.25) implies an option price of $3,125.

Like other debt options, buyers of puts on Eurodollar futures profit as rates move up and buyers of calls profit as rates move down. Consequently, institutions with liabilities or assets that float off short-term rates can use Eurodollar futures options to hedge their exposure to fluctuations in short-term rates. Consider institutions that have liabilities that float off short-term rates. These include banks and thrifts that issue CDs and/or take deposits based on money market rates. Also included are industrial and financial corporations that issue commercial paper, floating-rate notes, or preferred stock that floats off

money market rates. Likewise, those who make payments on adjustable-rate mortgages face similar risks.[2] In each instance, as short-term rates increase, the liability becomes more onerous for the borrower. Consequently, the issuers of these liabilities may need a means of capping their interest-rate expense. Although options on Eurodollar futures do not extend as far into the future as many issuers would like, they are effective tools for hedging many short-term rates over the near term. Consequently, an institution with floating-rate liabilities can buy an interest-rate *cap* by buying puts on Eurodollar futures. As rates move up, profits on the put position will tend to offset some or all of the incremental interest expense.

On the other side of the coin, and facing opposite risks, are the purchasers of floating-rate instruments—that is, investors who buy money market deposits, floating-rate notes, floating-rate preferred stock, and adjustable-rate mortgages. Investors who roll over CDs or commercial paper face the same problem. As rates fall, these investors receive less interest income. Consequently, they may feel a need to buy interest-rate *floors,* which are basically call options. As rates fall, calls on debt securities increase in value and will offset the lower interest income received by the investor.

In conclusion, options on Eurodollar futures can be used to limit the risk associated with fluctuations in short-term rates. This is accomplished by buying puts if the exposure is to rising rates, or by buying calls if the exposure is to falling rates.

Mechanics of Trading Futures Options

To take a position in futures options, one works with a futures broker. The types of orders that are used to buy or sell futures options are generally the same as the orders discussed for futures contracts. The clearinghouse associated with the exchange where the futures option is traded once again stands between the buyer and the seller. Furthermore, the commission costs and related issues that we discussed for futures also generally apply to futures options.

There are no margin requirements for the buyer of futures options, but the option price must be paid in full when the option is purchased. Because the option price is the maximum amount that the buyer can lose regardless of how adverse the price movement of the underlying futures contract, there is no need for margin.

Because the seller has agreed to accept all of the risk (and no reward other than the option premium) of the position in the underlying instrument, the seller generally is required to deposit not only the margin required for the underlying futures contract but also with certain exceptions, the option price as well. Furthermore, subsequent price changes adversely affecting the seller's position will lead to additional margin requirements.

2. To the extent that the interest-rate payment on an adjustable-rate mortgage has an upper and lower bound, the risk to issuers and investors is limited by the nature of the instrument.

OTC CONTRACTS

There is a substantial over-the-counter (OTC) market for fixed income options and forwards. (Forward contracts are the OTC equivalent of futures contracts.) For example, in the OTC market, one can easily buy or sell options on LIBOR, commercial paper, T-bill, and prime rates. One can buy and sell options on virtually any Treasury issue. One can buy and sell options on any number of mortgage securities. One can buy and sell options with expirations ranging from as short as one day to as long as 10 years. In the OTC market, one can easily take forward positions in three- and six-month LIBOR going out to about 2 years.

In the options market in particular, a natural division has evolved between the OTC market and the listed market. Given the relatively small number of futures contracts, the exchanges' need for standardization, and the synergy created by the futures options contract trading side by side with the underlying futures contract, the exchanges have been most successful with options on futures contracts. Because off-exchange options on futures are prohibited, futures options cannot be traded over the counter. On the other hand, because the OTC market is very good at creating flexible structures and handling a diversity of terms, the OTC market has been more successful than the exchanges in trading options on cash securities and on cash market interest rates.

In the following sections, we discuss the structure of the OTC fixed income derivative markets and their advantages and disadvantages relative to the exchange-traded markets. We also discuss the most important contracts traded in the OTC market. These are options on mortgage securities, options on cash Treasuries, caps and floors on LIBOR, and forward rate agreements on LIBOR.

The Structure of the OTC Market

As in other OTC markets, there is no central marketplace for OTC fixed income options and forward contracts. A transaction takes place whenever a buyer and seller agree to a price. Unlike an exchange transaction, the terms, size, and price of the contract generally remain undisclosed to other market participants. Accordingly, the OTC market is much less visible than the exchange markets and it is more difficult to ascertain the current market price for a given option or forward contract. Two groups, however, help to alleviate this problem. First, there are the OTC market makers. Market makers in OTC fixed income options and forwards are typically large investment banks and commercial banks. A market maker, by definition, stands ready to buy or sell a given option or forward contract to accommodate a client's needs. To be effective, the market maker must be willing and able to handle large orders and must keep the bid/ask spreads reasonably narrow.

The other group that helps bring order to the OTC market is the brokers. The sole job of the brokers is to bring together buyers and sellers; it is not the brokers' job to take positions in option and forward contracts. The buyers and sellers that the brokers bring together can be market makers or the end users of the contracts. To do their job, the brokers must distribute information about the prices where they

see trades taking place and the prices at which they believe further trades can be completed. This information is distributed to potential buyers and sellers over the phone and over publicly available media such as Telerate pages.

Because there is no central market for OTC fixed income options and forwards, there can be no clearinghouse. Consequently, those who position OTC contracts may have to give considerable weight to the creditworthiness of their counterparty. For example, entities that sell options or position forward rate agreements (FRAs) can have potential liabilities equal to several times their net worth. Furthermore, there is no guarantee that these counterparties have effective hedges against their positions or, in fact, that they are hedging at all. Furthermore, financial problems on the part of the counterparty can jeopardize the ability or willingness of the counterparty to make good on the terms of a contract even if it is hedged. Consequently, unlike the exchange-traded markets, where one neither knows nor cares who is on the other side of a trade, in the OTC market it is usually very important to know who is on the other side. Creditworthiness can be one of the most important considerations in the trade.

The potential credit problems associated with OTC trades are mitigated in a number of ways. First, some institutions will not buy options from or take either side of an FRA contract with any party other than a major entity with a sound credit rating. Second, some institutions require their counterparty to post collateral immediately after the transaction is completed. This collateral serves much the same purpose as initial margin in the futures and futures options market. Finally, some institutions reserve the right to call for additional collateral from their counterparties if the market moves against the counterparty. This is analogous to variation margin in the exchange-traded markets. Although these provisions may not be as good as a central clearinghouse, they are apparently good enough for a very large number of institutions and good enough for a very large market to develop.

Liquidity, in terms of being able to easily close out an existing position, can be a constraint in the OTC market. OTC options and forwards generally are not assignable transactions. Thus, for example, if one sells an option, the contingent liability associated with that option cannot be transferred to a third party without the express permission of the option buyer. If an option seller wants to cover a short option position, often the best strategy is to buy a similar option from a third party to offset the risks of the original option. However, if the credit of the offsetting party is in question, or the offsetting option is not identical, risks will remain for the option seller. The option buyer can face similar problems if closing out the option before expiration. Credit considerations and the fact that the option buyer may not be able to sell an identical option to offset the first option make it more difficult to effectively close out the long option position. Because FRAs involve contingent liabilities for both sides of the transaction, similar problems exist for both buyers and sellers of FRAs.

Some of the problems associated with the OTC market arise from the fact that the contracts are not standardized. However, nonstandardization leads to

many benefits as well. As indicated earlier, OTC contracts can be specified in virtually any terms that are acceptable to both buyer and seller. A potential buyer or seller thus can approach a market maker with whatever structure is needed and in many (but certainly not all) cases obtain the desired structure at a reasonable price. Compared to the very rigid structure of the exchange-traded markets, this is a remarkable advantage.

The OTC Contracts

Options on Mortgages

The OTC market for options on fixed income instruments began in the mid-1970s with *standby* commitments. Standbys were essentially put options on mortgages that allowed the holder (usually a mortgage banker) to sell mortgages at a given price during a given period of time. Although standbys were popularized by the Federal National Mortgage Association, other institutions soon got into the business of selling options. Thrift institutions, in particular, soon became sellers of puts, as well as calls, on mortgages. The thrift would typically sell out-of-the-money puts (struck at a yield that seemed attractive relative to current yields) and out-of-the-money calls (often struck at the thrift's cost of the underlying securities). Until the early 1980s, there were no real market makers in the OTC mortgage options market. Thus a trade typically did not occur until an end user who wanted to buy an option could be paired with an end user who wanted to sell the very same option. The intermediary who stood in between these two parties was usually not willing to position one side without the other.

Today, the market for options on mortgages includes many more participants, although the original standby commitments no longer exist. Investment banks and commercial banks now play a major role in the mortgage options market. Many of the large investment and commercial banks are now willing to position mortgage options without having the other side of the trade. This makes the market much more liquid and flexible than it would be otherwise. The end users of options on mortgages have not changed greatly, but the number of users has increased greatly. Mortgage bankers continue to buy puts on mortgages. Thrifts continue to sell both puts and calls. As some thrifts now play the role of mortgage banker, they too have become buyers of puts on mortgages. Money managers have also become a part of the market, usually as sellers of call options against mortgages in their portfolios.

The market for mortgage options today is composed almost entirely of options on the standard agency pass-through mortgage securities. Options on CMO tranches, IOs, POs, and the like are not a significant part of the OTC mortgage options market. The majority of the options traded are on 30-year mortgages, but options on 15-year products are also readily available. In terms of expiration, trading in mortgage options tends to be concentrated in the shorter expirations, with most of the options expiring within 60 days, and the vast majority expiring within one year. In terms of strike price, most of the trading is in at-the-money and out-of-the-money options.

Options on Treasury Securities

Although not as old as the OTC options market for mortgages, the OTC options market for Treasury securities is now just as large and liquid. As in the mortgage options market, investment banks and commercial banks play major roles as market makers, frequently standing ready to buy or sell options on $100 million (or more) of Treasury securities. Most of the action is in options expiring within 60 days, written at the money or out of the money. Options on Treasuries are concentrated in the on-the-run issues, with most of the remaining business being done in the off-the-run issues.

Except for the mortgage bankers, who have considerably less interest in options on Treasuries, the end users of options on Treasuries mirror the market for options on mortgages. Thrifts tend to be writers of out-of-the-money puts and calls, and money managers and mutual funds tend to be covered call writers.

Caps and Floors on LIBOR

The primary OTC options covering the short end of the yield-curve are the caps and floors on three- and six-month LIBOR. A cap on LIBOR is, in essence, a series of puts on LIBOR-based debt, whereas a floor on LIBOR is, in essence, a series of calls on LIBOR-based debt.

The buyer of a cap or floor holds most of the rights in the contract, as with other options. The seller of a cap or floor will of course receive an options premium from the buyer, but is then obligated to perform on the contract.

To see how these contracts work, consider a five-year, $100 million cap on three-month LIBOR struck at 4%. Such a contract will specify reset dates occurring every three months for a total of 20 resets. The first reset will usually occur immediately or within a couple of weeks of the trade date, and the last reset will usually be about three months before the stated maturity of the contract. To determine what the payoff to the cap buyer will be, on every reset date one compares the three-month LIBOR (taken from a predetermined source) with the 4% strike rate. If the three-month LIBOR is at or below 4%, nothing is owed to the cap buyer. However, if the three-month LIBOR is above 4%, the cap seller must pay the cap buyer the monetary value of the amount by which three-month LIBOR exceeds 4%. In this case, for a 90-day interest accrual period, the value of each basis point is $2,500 (from $0.0001 \times \$100{,}000{,}000 \times 90/360$). Thus, for example, if three-month LIBOR on a particular reset date is 4.50%, the cap seller owes the cap buyer $125,000 for that reset. If, on the next reset date, three-month LIBOR is 6%, the cap seller owes the cap buyer $500,000 for that reset. If, on the next reset date, three-month LIBOR is 3.50%, the cap seller owes nothing to the cap buyer for that reset. In most cases, the cap seller pays the cap buyer the amount of money owed for a particular reset at the end of the interest accrual period-in this case, three months after the reset date.

The mechanics of floors are similar, except that the payoff comes when rates fall below a given level, instead of when they rise above a given level. For example, if one buys a $25 million seven-year 3% floor on six-month LIBOR, there are a total of 14 reset dates. On each of these reset dates, one compares six-month

LIBOR to 3%. If six-month LIBOR is above 3%, nothing is owed to the buyer of the floor for that reset. However, if six-month LIBOR is below 3%, for a 180-day interest accrual period the floor seller owes the floor buyer $1,250 for every basis point by which six-month LIBOR is below 3% (from $0.0001 \times \$25{,}000{,}000 \times {}^{180}/_{360}$).

Like other OTC options markets, the cap and floor market is composed of market makers, end users, and brokers. The market makers are once again the large investment banks and commercial banks. However, there are fewer market makers and generally wider spreads in the cap and floor market than there are in the options market for mortgages or Treasury securities. Nonetheless, there is an active market out to 10 years, particularly for out-of-the-money caps and, to a lesser degree, out-of-the-money floors.

The end-user buyers of caps and floors are primarily institutions with risks that they need to cover. For example, institutions that fund short and lend long will tend to have losses as short-term rates rise. Similarly, businesses that fund by rolling over short-term obligations such as commercial paper or by bank borrowings tied to LIBOR or the prime rate will tend to have losses as short-term rates rise. These institutions, which include many thrifts, banks, and finance companies, as well as industrial and construction companies, can protect themselves against rising short-term rates by buying caps. End-user buyers of floors tend to be firms that face losses if rates fall. Such a case might occur, for example, if an institution borrows at a floating rate with a built-in floor. Such an institution may be structured so that floating rates, per se, pose no problem; the problem arises when the floating rate at which they borrow is no longer really floating because the floor has been hit. This institution may buy a floor so that it will receive monetary compensation from the floor seller whenever the floating rate falls below the floor rate, thus covering the risks of lower rates.

The sellers of caps and floors, other than the market makers, are quite varied. In some cases, sellers sell caps or floors outright to bring in premium income. Others sell caps and/or floors to smooth out the cash-flows on other fixed income instruments, such as certain derivative mortgage products. In other cases, sellers only implicitly sell the caps or floors. The following example illustrates both kinds of sellers.

When the cap market was developing, it quickly became obvious that there were many natural buyers of caps, but few natural sellers of caps. One successful effort to create sellers of caps occurred when investment bankers, who had many potential buyers of caps, realized that caps could be created as a derivative of the floating-rate note (FRN) market. Issuers of FRNs routinely issue notes reset off LIBOR. Furthermore, there were known buyers of *capped* FRNs; but of course, capped FRNs must have a higher coupon than uncapped FRNs to compensate the FRN buyer for the cap risk. If an issuer sells capped floating-rate notes, the issuer, in effect, buys a cap on LIBOR from the buyer of the FRN. This cap can then be sold to the investment banker, who in turn sells it to capbuying clients. The deals that took place took exactly this form. The investment bankers underwrote capped FRNs for certain FRN issuers who agreed to make caplike payments to their

investment banker. The banker then sold caps to another client but did not incur any market risks because the two sets of potential payments offset one another. Using part of the proceeds of the sale of the cap, the investment bank agreed to make payments to the issuer to bring the cost of the floating-rate debt down to a level below that of uncapped floating-rate notes. Thus the investment bankers, the issuers of the FRNs, the buyers of the FRNs, and the ultimate cap-buying clients all walked away with a satisfactory transaction.

Such a transaction illustrates how creative financing can be used to create a seller of an instrument when no obvious seller exists. In this example, the issuers of the FRNs are willing to sell caps, given the fact that they, in turn, find someone willing to sell the caps to them. The ultimate seller of caps is the buyer of the capped FRNs. The buyers of the FRNs are, however, only implicit sellers of caps in the sense that they never explicitly have a position in caps on their books.

This example, which is just one of dozens, shows how market makers explicitly and implicitly induce end users of financial products to buy or sell the instruments that allow the market makers to cover their positions in the OTC market. This is not to say that the market makers are taking advantage of the other parties to their trades. As is often the case, all parties to a transaction can come out ahead.

Forward Rate Agreements (FRAs)

The FRA market represents the OTC equivalent of the exchange-traded futures contracts on short-term rates. FRAs are a natural outgrowth of the interbank market for short-term funds. However, unlike the interbank market, virtually any creditworthy entity can buy or sell FRAs.

The liquid and easily accessible sector of the FRA market is for three- and six-month LIBOR. Rates are quoted widely for settlement starting one month forward, and settling once every month thereafter out to about six months forward. Thus, for example, on any given day forward rates are available for both three- and six-month LIBOR one month forward, covering, respectively, the interest period starting in one month and ending in four months, and the interest period starting in one month and ending in seven months. These contracts are referred to as 1×4 and 1×7 contracts. On the same day, there will be FRAs on three- and six-month LIBOR for settlement two months forward. These are the 2×5 and 2×8 contracts. Similarly, settlements occur three months, four months, five months, and six months forward for both three- and six-month LIBOR. These contracts are also denoted by the beginning and end of the interest period they cover.

On each subsequent day, contracts with the same type of structures, that is, contracts with one month, two months, and so on, to settlement date, are offered again. Thus, although on any given day a relatively limited number of structures are widely quoted, new contracts with new settlement dates are offered at the beginning of each day. This is quite different from the futures market, where the same contracts with the same delivery dates trade day after day.

As for other OTC debt instruments, there are market makers and brokers who make the market work. However, unlike the other OTC derivative instruments, in

the FRA market the commercial banks are clearly the dominant force among the market makers. This dominance is due to the ability of the banks to blend their FRA transactions into their interbank transactions and overall funding operations. Consequently, many banks are willing to quote on a much wider variety of structures than the standard structures explained above. One can choose maturities other than three- and six-month LIBOR, and one can choose many settlement dates other than at an even number of months in the future.

In most cases, FRAs are written so that no money changes hands until the settlement date. To determine the cash-flows on the settlement date, LIBOR taken from some predetermined source is compared to the LIBOR rate specified in the FRA contract. The actual dollar amount that changes hands is the dollar value of the difference between the two rates, *present valued* for a period equal to the maturity of the underlying LIBOR, either three or six months. The rationale behind present valuing is that if an FRA is used to hedge the rate on a deposit (or other short-term instrument), the loss (gain) due to a change in interest rates will be paid (saved) at the maturity of the deposit, not at the issue date. Thus, because cash payments on the FRA are made on the settlement date (which presumably is the same as the issue date of the deposit) the present value of the interest expense (or saving) on the deposit will equal the amount of money actually received or paid on the FRA.

Finally, one peculiarity of the FRA market deserves note. If one *buys* an FRA, one profits from an *increase* in rates, and if one *sells* an FRA, one profits from a *decline* in rates.

KEY POINTS

- A forward contract is an agreement for the future delivery of something at a specified price at the end of a designated period of time but differs from a futures contract in that it is nonstandardized and does not trade on an organized exchange.
- Parties to a forward contract are exposed to counterparty risk which is the risk that the counterparty will not satisfy its contractual obligations.
- A futures contract is an agreement between a buyer (seller) and an established exchange or its clearinghouse in which the buyer (seller) agrees to take (make) delivery of something at a specified price during a designated period of time.
- The parties to a futures contract are required to satisfy margin requirements.
- An investor who takes a long futures position realizes a gain when the futures price increases; an investor who takes a short futures position realizes a loss when the futures price decreases.
- For the Treasury bond futures contract, the underlying instrument is $100,000 par value of a hypothetical 20-year, 6% coupon Treasury bond.

- Conversion factors are used to adjust the invoice price of a Treasury bond futures contract to make delivery equitable to both parties.
- The short in a Treasury bond futures contract has several delivery options.
- The 2-year, 5-year, and 10-year Treasury note futures contracts are modeled after the Treasury bond futures contract.
- Three-month LIBOR is the underlying instrument for the Eurodollar futures contract. This futures contract is a cash settlement contract and is one of the most heavily traded futures contracts in the world.
- The federal funds futures contract is a cash settlement contract whose underlying is the average overnight federal funds for the delivery month.
- The underlying instrument for a swap futures contract is the notional price of the fixed-rate side of a 10-year interest rate swap that has a notional principal equal to $100,000 and that exchanges semiannual interest payments at a fixed annual rate of 6% for floating interest rate payments based on 3-month LIBOR.
- Interest rate options include options on fixed income securities and options on interest rate futures called futures options.
- Caps and floors are agreements between two parties whereby one party for an upfront fee agrees to compensate the other if a designated interest rate is different from a predetermined level.
- A forward rate agreement is an over-the-counter derivative instrument which is essentially a forward-starting loan, but with no exchange of principal, so the cash exchanged between the counterparties depend only on the difference in interest rates.
- The elements of an FRA are the FRA rate, reference rate, notional amount, contract period, and settlement date.
- The buyer of an FRA is agreeing to pay the FRA rate and the seller of the FRA is agreeing to receive the FRA rate. The amount that must be exchanged at the settlement date is the present value of the interest differential.
- In contrast to an interest rate futures contract, the buyer of an FRA benefits if the reference rate increases and the seller benefits if the reference rate decreases.

CHAPTER

MARK PITTS, PH.D.

BRUCE M. COLLINS, PH.D.
Professor of Finance
Western Connecticut State University

One of the primary concerns most traders and investors have when taking a position in futures contracts is whether the futures price at which they transact will be a fair price. Buyers are concerned that the price may be too high and that they will be picked off by more experienced futures traders waiting to profit from the mistakes of the uninitiated. Sellers worry that the price is artificially low and that savvy traders may have manipulated the markets so that they can buy at bargain-basement prices. Furthermore, prospective participants frequently find no rational explanation for the sometimes violent ups and downs that occur in the futures markets. Theories about efficient markets give little comfort to anyone who knows of or has experienced the sudden losses that can occur in the highly leveraged futures markets.

Fortunately, the futures markets are not as irrational as they may at first seem; if they were, they would not be so successful. The interest-rate futures markets are not perfectly efficient markets, but they probably come about as close as any market. Furthermore, there are very clear reasons why futures prices are what they are, and there are methods by which traders, investors, and borrowers will quickly eliminate any discrepancy between futures prices and their fair levels.

In this chapter we will explain how the fair or theoretical value of a futures contract is determined. We then explain several portfolio applications of interest-rate futures.

PRICING OF FUTURES CONTRACTS

There are several different ways to price futures contracts. Fortunately, all lead to the same fair price for a given contract. Each approach relies on the *law of one price.* This law states that a given financial asset (or liability) must have the same price

regardless of the means by which one goes about creating that asset (or liability). In this section we will demonstrate one way in which futures contracts can be combined with cash market instruments to create cash-flows that are identical to other cash securities.[1] The law of one price implies that the synthetically created cash securities must have the same price as the actual cash securities. Similarly, cash instruments can be combined to create cash-flows that are identical to futures contracts. By the law of one price, the futures contract must have the same price as the synthetic futures created from cash instruments.

Illustration of the Basic Principles

To understand how futures contracts should be priced, consider the following example. Suppose that a 20-year 100 par value bond with a coupon rate of 12% is selling at par. Also suppose that this bond is the deliverable for a futures contract that settles in three months. If the current three-month interest rate at which funds can be loaned or borrowed is 8% per year, what should be the price of this futures contract?

Suppose the price of the futures contract is 107. Consider the following strategy:

Sell the futures contract at 107.

Purchase the bond for 100.

Borrow 100 for three months at 8% per year.

The borrowed funds are used to purchase the bond, resulting in no initial cash outlay for this strategy. Three months from now, the bond must be delivered to settle the futures contract and the loan must be repaid. These trades will produce the following cash-flows:

From settlement of the futures contract	
Flat price of bond	107
Accrued interest (12% for three months)	+3
Total proceeds	110
From the loan	
Repayment of principal of loan	100
Interest on loan (8% for three months)	+2
Total outlay	102
Profit	8

1. For other ways to price futures contracts, see Chapter 5 in Mark Pitts and Frank J. Fabozzi, *Interest-Rate Futures and Options* (Chicago: Probus Publishing, 1990).

This strategy will guarantee a profit of 8. Moreover, the profit is generated with no initial outlay because the funds used to purchase the bond are borrowed. The profit will be realized *regardless of the futures price at the settlement date.* Obviously, in a well-functioning market, arbitrageurs would buy the bond and sell the futures, forcing the futures price down and bidding up the bond price so as to eliminate this profit. This strategy of purchasing a bond with borrowed funds and simultaneously selling a futures contract to generate an arbitrage profit is called a *cash and carry trade.*

In contrast, suppose that the futures price is 92 instead of 107. Consider the following strategy:

Buy the futures contract at 92.

Sell (short) the bond for 100.

Invest (lend) 100 for three months at 8% per year.

Once again, there is no initial cash outlay. Three months from now a bond will be purchased to settle the long position in the futures contract. That bond will then be used to cover the short position (i.e., to cover the short sale in the cash market). The outcome in three months would be as follows:

From settlement of the futures contract	
Flat price of bond	92
Accrued interest (12% for three months)	+3
Total outlay	95
From the loan	
Principal received from maturing investment	100
Interest earned from the three-month investment (8% for three months)	+2
Total proceeds	102
Profit	7

The 7 profit is a pure arbitrage profit. It requires no initial cash outlay and will be realized regardless of the futures price at the settlement date. Because this strategy involves initially selling the underlying bond, it is called a *reverse cash and carry trade.*

There is a futures price, however, that will eliminate the arbitrage profit. There will be no arbitrage if the futures price is 99. Let's look at what would happen if the two previous strategies were followed and the futures price were 99. First, consider following cash and carry trade:

Sell the futures contract at 99.

Purchase the bond for 100.

Borrow 100 for three months at 8% per year.

In three months, the outcome would be as follows:

From settlement of the futures contract	
Flat price of bond	99
Accrued interest (12% for three months)	+3
Total proceeds	102
From the loan	
Repayment of principal of the loan	100
Interest on the loan (8% for three months)	+2
Total outlay	102
Profit	0

There is no arbitrage profit.

Next, consider the following reverse cash and carry trade:

Buy the futures contract at 99.

Sell (short) the bond for 100.

Invest (lend) 100 for three months at 8% per year.

The outcome in three months would be as follows:

From settlement of the futures contract	
Flat price of bond	99
Accrued interest (12% for three months)	+3
Total outlay	102
From the loan	
Principal received from maturing investment	100
Interest earned from the three-month investment (8% for three months)	+2
Total proceeds	102
Profit	0

Thus neither strategy results in a profit. The futures price of 99 is the equilibrium price because any higher or lower futures price will permit arbitrage profits.

Theoretical Futures Price Based on Arbitrage Model

Considering the arbitrage arguments just presented, the equilibrium futures price can be determined on the basis of the following information:

- The price of the bond in the cash market.
- The coupon rate on the bond. In our example, the coupon rate was 12% per annum.

- The interest rate for borrowing and lending until the settlement date. The borrowing and lending rate is referred to as *the financing rate.* In our example, the financing rate was 8% per annum.

We will let

r = financing rate

c = current yield, or coupon rate divided by the cash market price

P = cash market price

F = futures price

t = time, in years, to the futures delivery date

and then consider the following cash and carry trade that is initiated on a coupon date:

Sell the futures contract at F.

Purchase the bond for P.

Borrow P until the settlement date at r.

The outcome at the settlement date is as follows:

From settlement of the futures contract	
Flat price of bond	F
Accrued interest	$+ctP$
Total proceeds	$F + ctP$
From the loan	
Repayment of principal of the loan	P
Interest on loan	$+ rtP$
Total outlay	$P + rtP$

The profit will equal

$$\text{Profit} = \text{total proceeds} - \text{total outlay}$$
$$\text{Profit} = F + ctP - (P + rtP)$$

In equilibrium, the theoretical futures price occurs where the profit from this strategy is zero. Thus, to have equilibrium, the following must hold:

$$0 = F + ctP - (P + rtP)$$

Solving for the theoretical futures price, we have

$$F = P + Pt(r - c) = P[1 + t(r - c)] \tag{60–1}$$

Alternatively, consider the following reverse cash and carry trade:

Buy the futures contract at F.

Sell (short) the bond for P.

Invest (lend) P at r until the settlement date.

The outcome at the settlement date would be as follows:

From settlement of the futures contract	
Flat price of bond	F
Accrued interest	$+ ctP$
Total outlay	$F + ctP$
From the loan	
Proceeds received from maturing of investment	P
Interest earned	$+ rtP$
Total proceeds	$P + rtP$

The profit will equal

$$\text{Profit} = \text{total proceeds} - \text{total outlay}$$
$$\text{Profit} = P + rtP - (F + ctP)$$

Setting the profit equal to zero so that there will be no arbitrage profit and solving for the futures price, we obtain the same equation for the futures price as Eq. (60–1).

Let's apply Eq. (60–1) to our previous example in which

$$r = 0.08$$
$$c = 0.12$$
$$P = 100$$
$$t = 0.25$$

Then the theoretical futures price is

$$F = 100 + 100 \times 0.25(0.08 - 0.12)$$
$$= 100 - 1 = 99$$

This agrees with the equilibrium futures price we derived earlier.

The theoretical futures price may be at a premium to the cash market price (higher than the cash market price) or at a discount from the cash market price (lower than the cash market price), depending on the value of $(r - c)$. The term $r - c$ is called the *net financing cost* because it adjusts the financing rate for the coupon interest earned. The net financing cost is more commonly called the *cost of carry,* or simply *carry. Positive carry* means that the current yield earned is greater than the financing

cost; *negative carry* means that the financing cost exceeds the current yield. The relationships can be expressed as follows:

Carry	Futures Price
Positive ($c > r$)	Will sell at a discount to the cash price ($F < P$)
Negative ($c < r$)	Will sell at a premium to the cash price ($F > P$)
Zero ($r = c$)	Will be equal to the cash price ($F = P$)

In the case of interest-rate futures, carry (the relationship between the short-term financing rate and the current yield on the bond) depends on the shape of the yield-curve. When the yield-curve is upward-sloping, the short-term financing rate will generally be less than the current yield on the bond, resulting in positive carry. The futures price will then sell at a discount to the cash price for the bond. The opposite will hold true when the yield-curve is inverted.

A Closer Look at the Theoretical Futures Price

To derive the theoretical futures price using the arbitrage argument, we made several assumptions. We will now discuss the implications of these assumptions.

Interim Cash-Flows. No interim cash-flows owing to variation margin or coupon interest payments were assumed in the model. However, we know that interim cash-flows can occur for both of these reasons. Because we assumed no variation margin, the price derived is technically the theoretical price for a forward contract (which is not marked to market at the end of each trading day). If interest rates rise, the short position in futures will receive margin as the futures price decreases; the margin can then be reinvested at a higher interest rate. In contrast, if interest rates fall, there will be variation margin that must be financed by the short position; however, because interest rates have declined, the financing can be done at a lower cost. Thus, whichever way rates move, those who are short futures gain relative to those who are short forward contracts that are not marked to market. Conversely, those who are long futures lose relative to those who are long forward contracts that are not marked to market. These facts account for the difference between futures and forward prices.

Incorporating interim coupon payments into the pricing model is not difficult. However, the value of the coupon payments at the settlement date will depend on the interest rate at which they can be reinvested. The shorter the maturity of the futures contract and the lower the coupon rate, the less important the reinvestment income is in determining the theoretical futures price.

The Short-Term Interest Rate (Financing Rate). In deriving the theoretical futures price, it is assumed that the borrowing and lending rates are equal. Typically, however, the borrowing rate is greater than the lending rate.

We will let

$$r_B = \text{borrowing rate}$$
$$r_L = \text{lending rate}$$

Consider the following strategy:

Sell the futures contract at F.

Purchase the bond for P.

Borrow P until the settlement date at r_B.

The futures price that would produce no arbitrage profit is

$$F = P + P\,(r_B - c) \tag{60–2}$$

Now consider the following strategy:

Buy the futures contract at F.

Sell (short) the bond for P.

Invest (lend) P at r_L until the settlement date.

The futures price that would produce no profit is

$$F = P + P(r_L - c) \tag{60–3}$$

Equations (60–2) and (60–3) together provide boundaries for the theoretical futures price. Equation (60–2) provides the upper boundary, and Eq. (60–3) the lower boundary. For example, assume that the borrowing rate is 8% per year, or 2% for three months, and the lending rate is 6% per year, or 1.5% for three months. Then, using Eq. (60–2) and the previous example, the upper boundary is

$$\begin{aligned} F(\text{upper boundary}) &= \$100 + \$100(0.02 - 0.03) \\ &= \$99 \end{aligned}$$

The lower boundary using Eq. (60–3) is

$$\begin{aligned} F(\text{lower boundary}) &= 100 + \$100(0.015 - 0.03) \\ &= \$98.50 \end{aligned}$$

In calculating these boundaries, we assumed no transaction costs were involved in taking the position. In actuality, the transaction costs of entering into and closing the cash position as well as the round-trip transaction costs for the futures contract, must be considered and do affect the boundaries for the futures contract.

Deliverable Bond and Settlement Date Unknown. In our example, we assumed that only one bond is deliverable and that the settlement date occurs three months from now. As explained in Chapter 59, futures contracts on Treasury bonds and Treasury notes are designed to allow the short position the choice of delivering one of a number of deliverable issues. Also, the delivery date is not known.

Because there may be more than one deliverable, market participants track the price of each deliverable bond and determine which is the cheapest to deliver. The futures price will then trade in relation to the bond that is cheapest to deliver.

The cheapest to deliver is the bond or note that will result in the smallest loss or the greatest gain if delivered by the short futures position.[2]

In addition to the reasons we have already discussed, there are several reasons why the actual futures price will diverge from the theoretical futures price based on the arbitrage model. First, there is the risk that although an issue may be the cheapest to deliver at the time a position in the futures contract is taken, it may not be the cheapest to deliver after that time. Thus, there will be a divergence between the theoretical futures price and the actual futures price. A second reason for this divergence is the other delivery options granted the short position. Finally, there are biases in the CME conversion factors.

Deliverable Is a Basket of Securities. The municipal index futures contract is a cash settlement contract based on a basket of securities. The difficulty in arbitraging this futures contract is that it is too expensive to buy or sell every bond included in the index. Instead, a portfolio containing a smaller number of bonds may be constructed to track the index. The arbitrage, however, is no longer risk-free because there is the risk that the portfolio will not track the index exactly. This is referred to as *tracking-error risk.* Another problem in constructing the portfolio so that the arbitrage can be performed is that the composition of the index is revised periodically. Therefore, anyone using this arbitrage trade must constantly monitor the index and periodically rebalance the constructed portfolio.

APPLICATIONS TO PORTFOLIO MANAGEMENT

This section describes various ways in which a money manager can use interest-rate futures contracts.

Interest-Rate Risk Control

Interest-rate risk control is probably the most common use of interest rate futures. This is accomplished by altering the portfolio's duration. Money managers who have strong expectations about the direction of interest rates will adjust the duration of their portfolio to capitalize on their expectations. Specifically, if they expect interest rates to increase, they will shorten the duration of the portfolio; if they expect interest rates to decrease, they will lengthen the duration of the portfolio. Also, anyone using structured portfolio strategies must periodically adjust the portfolio duration to match the duration of some benchmark.

Although money managers can alter the duration of their portfolios with cash market instruments, a quick and less expensive means for doing so (especially on a temporary basis) is to use futures contracts. By buying futures contracts

2. An alternative procedure is to compute the implied (break-even) repo rate. This rate is the yield that would produce no profit or loss if the bond were purchased and a futures contract were sold against the bond. The cheapest-to-deliver bond is the one with the highest implied repo rate.

on Treasury bonds or notes, they can increase the duration of the portfolio. Conversely, they can shorten the duration of the portfolio by selling futures contracts on Treasury bonds or notes.

Hedging

Hedging is a special case of interest-rate risk control whereby the manager seeks to obtain a duration of zero.[3] Hedging with futures involves taking a futures position as a temporary substitute for transactions to be made in the cash market at a later date. If cash and futures prices move together, any loss realized by the hedger from one position (whether cash or futures) will be offset by a profit on the other position. When the net profit or loss from the positions are exactly as anticipated, the hedge is referred to as a *perfect hedge.*

In practice, hedging is not that simple. The amount of net profit will not necessarily be as anticipated. The outcome of a hedge will depend on the relationship between the cash price and the futures price when a hedge is placed and when it is lifted. The difference between the cash price and the futures price is called the basis. The risk that the basis will change in an unpredictable way is called *basis risk.*

In most hedging applications, the bond to be hedged is not identical to the bond underlying the futures contract. This kind of hedging is referred to as *cross-hedging.* There may be substantial basis risk in cross-hedging. An unhedged position is exposed to price risk, the risk that the cash market price will move adversely. A hedged position substitutes basis risk for price risk.

A short (or sell) hedge is used to protect against a decline in the cash price of a fixed income security. To execute a short hedge, futures contracts are sold. By establishing a short hedge, the hedger has fixed the future cash price and transferred the price risk of ownership to the buyer of the futures contract. As an example of why a short hedge would be executed, suppose that a pension fund manager knows that bonds must be liquidated in 40 days to make a $5 million payment to the beneficiaries of the pension fund. If interest rates rise during the 40-day period, more bonds will have to be liquidated to realize $5 million. To guard against this possibility, the manager would sell bonds in the futures market to lock in a selling price.

A long (or buy) hedge is undertaken to protect against an increase in the cash price of a fixed income security. In a long hedge, the hedger buys a futures contract to lock in a purchase price. A pension fund manager may use a long hedge when substantial cash contributions are expected and the manager is concerned that interest rates will fall. Also, a money manager who knows that bonds are maturing in the near future and expects that interest rates will fall can employ a long hedge to lock in a rate.

3. Hedging is discussed in more detail in Chapter 61.

Asset Allocation

A pension sponsor may wish to alter the composition of the pension fund's assets between stocks and bonds. An efficient means of changing asset allocation is to use financial futures contracts: interest-rate futures and stock index futures.

Creating Synthetic Securities for Yield Enhancement

A cash market security can be synthetically created by using a position in the futures contract together with the deliverable instrument. The yield on the synthetic security should be the same as the yield on the cash market security. If there is a difference between the two yields, it can be exploited so as to enhance the yield on the portfolio.

To see how, consider an investor who owns a 20-year Treasury bond and sells Treasury futures that call for the delivery of that particular bond three months from now. The maturity of the Treasury bond is 20 years, but the investor has effectively shortened the maturity of the bond to three months.

Consequently, the long position in the 20-year bond and the short futures position are equivalent to a long position in a three-month riskless security. The position is riskless because the investor is locking in the price that he or she will receive three months from now—the futures price. By being long the bond and short the futures, the investor has synthetically created a three-month Treasury bill. The return the investor should expect to earn from this synthetic position should be the yield on a three-month Treasury bill. If the yield on the synthetic three-month Treasury bill is greater than the yield on the cash market Treasury bill, the investor can realize an enhanced yield by creating the synthetic short-term security. The fundamental relationship for creating synthetic securities is as follows:

$$\text{RSP} = \text{CBP} - \text{BFP} \tag{60–4}$$

where

CBP = cash bond position
BFP = bond futures position
RSP = riskless short-term security position

A negative sign before a position means a short position. In terms of our previous example, CBP is the long cash bond position, the negative sign before BFP refers to the short futures position, and RSP is the riskless synthetic three-month security or Treasury bill.

Equation (60–4) states that an investor who is long the cash market security and short the futures contract should expect to earn the rate of return on a risk-free security with the same maturity as the futures delivery date. Solving Eq. (60–4) for the long bond position, we have

$$\text{CBP} = \text{RSP} + \text{BFP} \tag{60–5}$$

Equation (60–5) states that a cash bond position equals a short-term riskless security position plus a long bond futures position. Thus a cash market bond can be synthetically created by buying a futures contract and investing in a Treasury bill.

Solving Eq. (60–5) for the bond futures position, we have

$$\text{BFP} = \text{CBP} - \text{RSP} \tag{60–6}$$

Equation (60–6) tells us that a long position in the futures contract can be synthetically created by taking a long position in the cash market bond and shorting the short-term riskless security. Shorting the short-term riskless security is equivalent to borrowing money. Notice that it was Eq. (60–6) that we used in deriving the theoretical futures price when the futures was overpriced. Recall that when the futures price was 107, the strategy to obtain an arbitrage profit was to sell the futures contract and create a synthetic long futures position by buying the bond with borrowed funds. This is precisely what Eq. (60–6) states. In this case, instead of creating a synthetic cash market instrument as we did with Eqs. (60–4) and (60–5), we have created a synthetic futures contract. The fact that the synthetic long futures position was cheaper than the actual long futures position provided an arbitrage opportunity.

If we reverse the sign of both sides of Eq. (60–6), we can see how a short futures position can be synthetically created.

In an efficient market, the opportunities for yield enhancement should not exist very long. Even in the absence of yield enhancement, however, synthetic securities can be used by money managers to hedge a portfolio position that they find difficult to hedge in the cash market either because of lack of liquidity or because of other constraints.

PORTABLE ALPHA

There are two basic approaches to investment management: passive and active. The objective of passive management is to match the performance of a benchmark that represents a defined asset class while the objective of active management is to select individual assets that are likely to perform better than the average. The returns to an active strategy will consist of returns based on market exposure and returns based on selection skill. The returns resulting from superior selection skills are referred to as *alpha*. Pure alpha strategies are those with no market risk and thus returns do not depend on market direction. An example is a long/short strategy that is market neutral.

In a period when equity markets have increased volatility and lower prospects for increasing returns, institutional investors look to reallocate funds to asset classes with lower volatility such as fixed income securities. Moreover, institutional investors confront an environment of funding shortfalls and moderate returns, which necessitates the development of alternative and more efficient sources of returns. *Portable alpha strategies* can be employed to maintain exposure to a lower volatility asset class while producing returns that approach equities.

The portable alpha strategy can either be used as a core investment in an asset class or as an overlay strategy.

Portable alpha strategies refer to an investment methodology or process that blends traditional asset class exposure with alternative investment strategies in order to add returns without assuming additional risk. The concept is "portable" in the sense that the integration of alternative with traditional does not impact management style or acceptable risk parameters adversely, which means it is easily transferred into an existing asset class or benchmark through the application of an overlay program to achieve the targeted asset exposure. Thus, the alpha is created independently of the core portfolio and transferred with the use of derivatives in order to maintain the characteristics of the core portfolio.

The significance of portable alpha strategies is that the asset allocation decision can be separated from the search for alpha within the asset class. Thus, portable alpha is a return enhancement strategy and not an asset substitution strategy. The advantage of the portable alpha approach is its flexibility in terms of adding returns without additional risk.[4] Many portable alpha strategies involve long and short positions. Exchange-traded futures contracts can be integral to a portable alpha strategy either as a means to overlay an existing core portfolio or as a means to synthetically maintain the core exposure to the fixed income asset class.[5]

The basis of "portable" alpha is that it explicitly changes the investment management process by separating the management of market returns and pure alpha returns.[6] Pure alpha strategies are factor or market neutral and have no correlation with market direction. The objective of portable alpha strategies is to improve the efficiency of finding positive incremental returns. For equity strategies it involves stock selection and for fixed income it might involve bond selection or the exploitation of yield-curve inefficiencies. In any case, derivatives including futures and swaps are vital to achieve the strategic asset allocation exposures. This paradigm shift that explicitly separates market returns and alpha has implications for manager selection and risk management.

Since alpha is the total return less market returns, the production of alpha does not depend on market direction and therefore positive alpha is possible in all market environments. The portable alpha strategy can be implemented as an overlay on an existing asset class or as a separate investment that uses swaps and futures to maintain the overall strategic asset allocation mix. Theoretically, portable alpha strategies can be produced from any strategy assuming it contains

4. Furthermore, the implementation of portable alpha strategies significantly expands the universe of managers beyond the limitations imposed by style or orientation.
5. For an example of a portable alpha overlay strategy see, Edgar E. Peters and Perr J. Vieth, "Portable Alpha Overlay Via PanAgora's Fixed Income Active Core Strategy," PanAgora Asset Management, undated.
6. See Adele Kohler, "Implementation Guide for Portable Alpha and Efficient Beta Exposure," State Street Global Advisors, undated.

alpha and there is sufficient liquidity to implement the strategy. Thus, there are three basic ways to develop a portable alpha generating strategy.

1. Identify an alpha generating long portfolios, use futures to eliminate market risk and overlay the strategy on the existing asset class.
2. Identify pure alpha generating investments from the hedge fund or fund of fund communities, sell off a portion of the asset class, and replace with futures and alpha generating investments.
3. Replace entire asset class with pure alpha generating strategies and use derivatives to maintain targeted market exposure.

Portable alpha represents a change in the investment process and a different way to think about risk and return. Futures contracts are an integral part of the implementation of many portable alpha investment programs.

KEY POINTS

- The theoretical futures price is determined by the net financing cost, or carry.
- Carry is the difference between the financing cost and the cash yield on the underlying cash instrument.
- The basic futures pricing model must be modified to account for nuances of specific futures contracts.
- Uses of futures contracts by portfolio managers are altering a portfolio's duration (risk control), asset allocation, creation of synthetic securities to enhance returns, and portable alpha.
- Hedging is a special case of controlling interest-rate risk in which the portfolio wants to alter the portfolio's duration to zero.
- Portable alpha strategies can be employed to maintain exposure to a lower volatility asset class while producing returns that approach equities.

CHAPTER
SIXTY-ONE

CONTROLLING INTEREST-RATE RISK WITH FUTURES AND OPTIONS

FRANK J. FABOZZI, PH.D., CFA
Professor of Finance
EDHEC Business School

SHRIKANT RAMAMURTHY
Consultant

MARK PITTS, PH.D.

In Chapter 59 the features and characteristics of interest-rate futures and options were explained. In this chapter, our focus is on how these derivative instruments can be used to control the interest-rate risk of a portfolio.

CONTROLLING INTEREST-RATE RISK WITH FUTURES

The price of an interest-rate futures contract moves in the opposite direction from the change in interest rates: when rates rise, the futures price will fall; when rates fall, the futures price will rise. By buying a futures contract, a portfolio's exposure to a rate increase is increased. That is, the portfolio's duration increases. By selling a futures contract, a portfolio's exposure to a rate increase is decreased. Equivalently, this means that the portfolio's duration is reduced. Consequently, buying and selling futures can be used to alter the duration of a portfolio.

While managers can alter the duration of their portfolios with cash-market instruments (buying or selling Treasury securities), using interest-rate futures

This chapter is adapted from an article by the authors appearing in *Professional Perspectives on Fixed Income Portfolio Management,* Vol. 1 (New Hope, PA: Frank J. Fabozzi Associates, 2000).

instead of trading long-term Treasuries themselves has the following three advantages:

Advantage 1: Transaction costs for trading futures are lower than trading in the cash market.

Advantage 2: Margin requirements are lower for futures than for Treasury securities; using futures thus permits greater leverage.

Advantage 3: It is easier to sell short in the futures market than in the Treasury market.

Futures also can be used in constructing a portfolio with a longer duration than is available with cash-market securities. For example, suppose that in a certain interest-rate environment a pension fund manager must structure a portfolio to have a duration of 15 to accomplish a particular investment objective. Bonds with such a long duration may not be available. By buying the appropriate number and kind of interest-rate futures contracts, a pension fund manager can increase the portfolio's duration to the target level of 15.

General Principles of Interest-Rate Risk Control

The general principle in controlling interest-rate risk with futures is to combine the dollar exposure of the current portfolio and the dollar exposure of a futures position so that the total dollar exposure is equal to the target dollar exposure. This means that the manager must be able to accurately measure the dollar exposure of both the current portfolio and the futures contract employed to alter the exposure.

There are two commonly used measures for approximating the change in the dollar value of a bond or bond portfolio to changes in interest rates: price value of a basis point (PVBP) and duration. PVBP is the dollar price change resulting from a 1 basis point change in yield. Duration is the approximate percentage change in price for a 100 basis point change in rates. (Given the percentage price change, the dollar price change for a given change in interest rates can be computed.) There are two measures of duration: *modified* and *effective*. Effective duration is the appropriate measure that should be used for bonds with embedded options. In this chapter when we refer to duration, we mean effective duration. Moreover, since the manager is interested in dollar price exposure, it is the effective *dollar* duration that should be used. For a 1 basis point change in rates, PVBP is equal to the effective dollar duration for a 1 basis point change in rates.

To estimate the effective dollar duration, it is necessary to have a good valuation model. It is the valuation model that is used to determine what the new values for the bonds in the portfolio will be if rates change. The difference between the current values of the bonds in the portfolio and the new values estimated by the valuation model when rates are changed is the dollar price exposure. Consequently, the starting point in controlling interest-rate risk is the development of a reliable valuation model. A reliable valuation model also is needed to

value the derivative contracts that the manager wants to use to control interest-rate exposure.

Suppose that a manager seeks a *target duration* for the portfolio based on either expectations of interest rates or client-specified exposure. Given the target duration, a target dollar duration for a small basis point change in interest rates can be obtained. For a 50 basis point change in interest rates, for example, the target dollar duration can be found by multiplying the dollar value of the portfolio by the target duration and then dividing by 200. For example, suppose that the manager of a $500 million portfolio wants a target duration of 6. This means that the manager seeks a 3% change in the value of the portfolio for a 50 basis point change in rates (assuming a parallel shift in rates of all maturities). Multiplying the target duration of 6 by $500 million and dividing by 200 gives a target dollar duration of $15 million.

The manager then must determine the dollar duration of the current portfolio. The current dollar duration for a 50 basis point change in interest rates is found by multiplying the current duration by the dollar value of the portfolio and dividing by 200. Thus, for our $500 million portfolio, suppose that the current duration is 4. The current dollar duration is then $10 million (4 times $500 million divided by 200).

The target dollar duration is then compared with the current dollar duration. The difference between the two dollar durations is the dollar exposure that must be provided by a position in the futures contract. If the target dollar duration exceeds the current dollar duration, a futures position must increase the dollar exposure by the difference. To increase the dollar exposure, an appropriate number of futures contracts must be purchased. If the target dollar duration is less than the current dollar duration, an appropriate number of futures contracts must be sold. That is,

If target dollar duration − current dollar duration > 0, buy futures

If target dollar duration − current dollar duration < 0, sell futures

Once a futures position is taken, the *portfolio's dollar duration* is equal to the *current dollar duration without futures* plus the *dollar duration of the futures position*. That is,

Portfolio's dollar return = current dollar duration without futures
+ dollar duration of futures position

The objective is to control the portfolio's interest-rate risk by establishing a futures position such that the portfolio's dollar duration is equal to the target dollar duration. Thus

Portfolio's dollar duration = target dollar duration

Or equivalently,

Target dollar duration = current dollar duration without futures
+ dollar duration of futures position (61–1)

Over time, the portfolio's dollar duration will move away from the target dollar duration. The manager can alter the futures position to adjust the portfolio's dollar duration to the target dollar duration.

Determining the Number of Contracts

Each futures contract calls for delivery of a specified amount of the underlying instrument. When interest rates change, the value of the underlying instrument changes, and therefore, the value of the futures contract changes. How much the futures dollar value will change when interest rates change must be estimated. This amount is called the *dollar duration per futures contract*. For example, suppose that the futures price of an interest-rate futures contract is 70 and that the underlying interest-rate instrument has a par value of $100,000. Thus the futures delivery price is $70,000 (0.70 times $100,000). Suppose that a change in interest rates of 50 basis points results in the futures price changing by about $0.03 per contract. Then the dollar duration per futures contract is $2,100 (0.03 times $70,000).

The dollar duration of a futures position is then the number of futures contracts multiplied by the dollar duration per futures contract. That is,

$$\text{Dollar duration of futures position} = \text{number of futures contracts} \times \text{dollar duration per futures contract} \qquad (61\text{–}2)$$

How many futures contracts are needed to obtain the target dollar duration? Substituting Eq. (61–2) into Eq. (61–1), we get

$$\text{Number of futures contracts} \times \text{dollar duration per futures contract} = \text{target dollar duration} - \text{current dollar duration without futures} \qquad (61\text{–}3)$$

Solving for the number of futures contracts, we have

$$\text{Number of futures contracts} = \frac{\text{target dollar duration} - \text{current dollar duration without futures}}{\text{dollar duration per futures more contract}} \qquad (61\text{–}4)$$

Equation (61–4) gives the approximate number of futures contracts that are necessary to adjust the portfolio's dollar duration to the target dollar duration. A positive number means that the futures contract must be purchased; a negative number means that the futures contract must be sold. Notice that if the target dollar duration is greater than the current dollar duration without futures, the numerator is positive, and therefore, futures contracts are purchased. If the target dollar duration is less than the current dollar duration without futures, the numerator is negative, and therefore, futures contracts are sold.

Dollar Duration for a Futures Position

Now we turn to how to measure the dollar duration of a bond futures position. Keep in mind what the goal is: it is to measure the sensitivity of a bond futures position to changes in rates.

The general methodology for computing the dollar duration of a futures position for a given change in interest rates is straightforward given a valuation model. The procedure is the same as for computing the dollar duration of any cash-market instrument—shock (change) interest rates up and down by the same number of basis points and determine the average dollar price change.

An adjustment is needed for the Treasury bond and note futures contracts. The pricing of the futures contract depends on the cheapest-to-deliver (CTD) issue.[1] Calculation of the dollar duration of a Treasury bond or note futures contract requires determining the impact of a change in interest rates will have on the price of a futures contract, which, in turn, affects how the futures price will change. The dollar duration of a Treasury bond and note futures contract is determined as follows:

$$\text{Dollar duration of futures contract} = \text{dollar duration of the CTD issue} \times \frac{\text{dollar duration of futures contract}}{\text{dollar duration of the CTD issue}}$$

There is a conversion factor for each issue that is acceptable for delivery for the futures contract. The conversion factor makes deliverable equitable to both the buyer and seller of the futures contract. For each deliverable issue, the product of the futures price and the conversion factor is the adjusted futures price for the issue. This adjusted price is called the *converted price*. Relating this to the preceding equation, the second ratio is approximately equal to the conversion factor of the cheapest-to-deliver issue. Thus we can write

$$\text{Dollar duration of futures contract} = \text{dollar duration of the CTD issue} \times \text{conversion factor for the CTD issue}$$

Why did we focus on dollar duration rather than duration? Recall that duration is the approximate percentage change in price. But what is the price of this leveraged instrument? The investor does not put up the full price of the position in order to acquire the position. Only the initial margin need be made in cash or a cash equivalent. Consequently, what is the base investment made by the investor? Rather than debate what should be used as the base investment in order to compute duration, let's simply ask why we are interested in calculating the exposure to changes in rates. As we have emphasized, it is to determine how a futures position will alter the exposure of a portfolio to changes in rates. Once we know how a futures position changes the dollar duration of a portfolio, we can determine for a portfolio its dollar duration. Given the funds invested by the investor in the portfolio, the portfolio's duration can be computed.

1. The cheapest-to-deliver issue is the one issue from among all those that are deliverable to satisfy a contract that has the highest return in a cash and carry trade. This return is called the *implied repo rate*.

Hedging with Interest-Rate Futures

Hedging with futures calls for taking a futures position as a temporary substitute for transactions to be made in the cash market at a later date. If cash and futures prices move together, any loss realized by the hedger from one position (whether cash or futures) will be offset by a profit on the other position. *Hedging is a special case of controlling interest-rate risk. In a hedge, the manager seeks a target duration or target dollar duration of zero.*

A *short hedge* (or *sell hedge*) is used to protect against a decline in the cash price of a bond. To execute a short hedge, futures contracts are sold. By establishing a short hedge, the manager has fixed the future cash price and transferred the price risk of ownership to the buyer of the futures contract. To understand why a short hedge might be executed, suppose that a pension fund manager knows that bonds must be liquidated in 40 days to make a $5 million payment to beneficiaries. If interest rates rise during the 40-day period, more bonds will have to be liquidated at a lower price than today to realize $5 million. To guard against this possibility, the manager can sell bonds in the futures market to lock in a selling price.

A *long hedge* (or *buy hedge*) is undertaken to protect against an increase in the cash price of a bond. In a long hedge, the manager buys a futures contract to lock in a purchase price. A pension fund manager might use a long hedge when substantial cash contributions are expected, and the manager is concerned that interest rates will fall. Also, a money manager who knows that bonds are maturing in the near future and expects that interest rates will fall can employ a long hedge to lock in a rate for the proceeds to be reinvested.

In bond portfolio management, typically the bond or portfolio to be hedged is not identical to the bond underlying the futures contract. This type of hedging is referred to as *cross-hedging*.

The hedging process can be broken down into four steps:

Step 1. Determining the appropriate hedging instrument

Step 2. Determining the target for the hedge

Step 3. Determining the position to be taken in the hedging instrument

Step 4. Monitoring and evaluating the hedge

We discuss each step below.

Determining the Appropriate Hedging Instrument

A primary factor in determining which futures contract will provide the best hedge is the degree of correlation between the rate on the futures contract and the interest rate that creates the underlying risk that the manager seeks to eliminate. For example, a long-term corporate bond portfolio can be better hedged with Treasury bond futures than with Treasury bill futures because long-term corporate bond rates are more highly correlated with Treasury bond futures than Treasury bill futures. Using the right delivery month is also important. A manager trying to lock

in a rate or price for September will use September futures contracts because September futures contracts will give the highest degree of correlation.

Correlation is not, however, the only consideration if the hedging program is of significant size. If, for example, a manager wants to hedge $600 million of a cash position in a distant delivery month, liquidity becomes an important consideration. In such a case, it might be necessary for the manager to spread the hedge across two or more different contracts.

Determining the Target for the Hedge

Having determined the right contract and the right delivery months, the manager then should determine what is expected from the hedge—that is, what rate will, on average, be locked in by the hedge. This is the *target rate* or *target price.* If this target rate is too high (if hedging a future sale) or too low (if hedging a future purchase), hedging may not be the right strategy for dealing with the unwanted risk. Determining what is expected (calculating the target rate or price for a hedge) is not always simple. We'll see how a manager should approach this problem for both simple and complex hedges.

Risk and Expected Return in a Hedge. When a manager enters into a hedge, the objective is to "lock in" a rate for the sale or purchase of a security. However, there is much disagreement about what rate or price a manager should expect to lock in when futures are used to hedge. Here are the two views:

View 1. The manager can, on average, lock in the current spot rate for the security (i.e., current rate in the cash market).

View 2. The manager can, on average, lock in the rate at which the futures contracts are bought or sold.

The truth usually lies somewhere in between these two views. However, as the following cases illustrate, each view is entirely correct in certain situations.

The Target for Hedges Held to Delivery. Hedges that are held until the futures delivery date provide an example of a hedge that locks in the futures rate (i.e., the second view). The complication in the case of using Treasury bond futures and Treasury note futures to hedge the value of intermediate- and long-term bonds is that because of the delivery options the manager does not know for sure when delivery will take place or which bond will be delivered. This is because of the delivery options granted to the short.[2]

To illustrate how a Treasury bond futures held to the delivery date locks in the futures rate, assume for the sake of simplicity that the manager knows which Treasury bond will be delivered and that delivery will take place on the last day of the delivery month. Suppose that for delivery on the September 1999 futures

2. These delivery options are explained in Chapter 59.

contract, the conversion factor for a deliverable Treasury issue is 1.283, implying that the investor who delivers this issue would receive from the buyer 1.283 times the futures settlement price plus accrued interest. An important principle to remember is that at delivery, the spot price and the futures price times the conversion factor must converge. *Convergence* refers to the fact that at delivery there can be no discrepancy between the spot price and futures price for a given security. If convergence does not take place, arbitrageurs would buy at the lower price and sell at the higher price and earn risk-free profits. Accordingly, a manager could lock in a September 1999 sale price for this issue by selling Treasury bond futures contracts equal to 1.283 times the par value of the bonds. For example, $100 million face value of this issue would be hedged by selling $128.3 million face value of bond futures (1,283 contracts).

The sale price that the manager locks in would be 1.283 times the futures price. This is the converted price. Thus, if the futures price is 113 when the hedge is set, the manager locks in a sale price of 144.979 (113 times 1.283) for September 1999 delivery, regardless of where rates are in September 1999. Exhibit 61–1 shows the cash-flows for a number of final prices for this issue and illustrates how cash-flows on the futures contracts offset gains or losses relative to the target price of 144.979.

Let's look at all the columns in Exhibit 61–1 and explain the computations for one of the scenarios—that is, for one actual sale price for the 11¼% Treasury bond. Consider the first actual sale price of 140. By convergence, at the delivery date the final futures price shown in column (2) must equal the Treasury bond's actual sale price adjusted by the conversion factor. Specifically, the adjustment is as follows. We know that

$$\text{Converted price} = \text{Treasury bond's price} \times \text{conversion factor}$$

and by convergence

$$\text{Final futures price} = \text{converted price}$$

so that

$$\text{Final futures price} = \text{Treasury bond's actual sale price} \times \text{conversion factor}$$

Thus, to compute the final futures price in column (2) of Exhibit 61–1 given the Treasury bond's actual sale price in column (1), the following is computed:

$$\text{Final futures price} = \frac{\text{Treasury bonds actual sale price}}{\text{conversion factor}}$$

Since the conversion factor is 1.283 for the 11¼% Treasury issue, for the first actual sale price of 140, the final futures price is

$$\text{Final futures price} = \frac{140}{1.283} = 109.1193$$

Column (3) shows the market value of the Treasury bonds. This is found by multiplying the actual sale price in column (1) by 100 to obtain the actual sale

EXHIBIT 61–1

Treasury Issue Hedge Held to Delivery

Instrument to be hedged: $100 million 11¼% Treasury Bonds of 2/15/15
Conversion factor for September 1999 = 1.283
Price of futures contract when sold = 113
Target price = (1.283 × 113) = 144.979
Par value hedged = $100,000,000
Number of futures contracts = 1,283
Futures position = Target = $144,979,000

*By convergence, must equal bond price divided by the conversion factor.
†Bond futures trade in even increments of 1/32. Accordingly, the futures prices and margin flows are only approximate.
‡Transaction costs and the financing of margin flows are ignored.

price per $1 of par value and then multiplying by the $100 million par value. That is,

$$\text{Market value of Treasury bonds} = (\text{actual sale price}/100) \times \$100{,}000{,}000$$

For the actual sale price of 140, the value in column (3) is

$$\begin{aligned}\text{Market value of Treasury bonds} &= (140/100) \times \$100{,}000{,}000 \\ &= \$140{,}000{,}000\end{aligned}$$

Column (4) shows the value of the futures position at the delivery date. This value is computed by first dividing the futures price shown in column (2) by

100 to obtain the futures price per $1 of par value. Then this value is multiplied by the par value per contract of $100,000 and further multiplied by the number of futures contracts. That is,

Value of futures position

$$= (\text{final futures price}/100) \times \$100,0000 \times \text{number of futures contracts}$$

In our illustration, the number of futures contracts is 1,283. For the actual sale price of the bond of 140, the final futures price is 109.1193. Thus, the value shown in column (4) is

$$\begin{aligned}\text{Value of futures position} &= (109.1193/100) \times \$100,000 \times 113 \\ &= \$140,000,062\end{aligned}$$

The value shown in column (4) is $140,000,000 because the final futures price of 109.1193 was rounded. Using more decimal places, the value would be $140,000,000.

Now let's look at the gain or loss from the futures position. This value is shown in column (5). Recall that the futures contract was shorted. The futures price at which the contracts were sold was 113. Thus, if the final futures price exceeds 113, this means that there is a loss on the futures position—that is, the futures contract is purchased at a price greater than for which it was sold. In contrast, if the futures price is less than 113, this means that there is a gain on the futures position—that is, the futures contract is purchased at a price less than for which it was sold. The gain or loss is determined by the following formula:

$$(113/100 - \text{final futures price}/100) \times \$100,000 \times \text{number of futures contracts}$$

In our illustration, for a final futures price of 109.1193 and 1,283 futures contracts, we have

$$(113/100 - 109.1193/100) \times \$100,000 \times 1,283 = \$4,978,938.1$$

The value shown in column (5) is $4,979,000 because that is the more precise value using more decimal places for the final futures price than shown in Exhibit 61–1. The value is positive which means that there is a gain in the futures position. Note that for all the final futures prices above 113 in Exhibit 61–1, there is a negative value, which means that there is a loss on the futures position.

Finally, column (6) shows the effective sale price for the Treasury bond. This value is found as follows:

Effective sale price for Treasury bond

$$= \text{actual sale price of Treasury bond} + \text{gain or loss on futures position}$$

For the actual sale price of $140 million, the gain is $4,979,000. Therefore, the effective sale price for the Treasury bond is

$$\$140,000,000 + \$4,979,000 = \$144,979,000$$

Note that this is the target price for the Treasury bond. In fact, it can be seen from column (6) of Exhibit 61–1 that the effective sale price for all the actual sale prices for the Treasury bond is the target price. However, the target price is determined by the futures price, so the target price may be higher or lower than the cash (spot) market price when the hedge is set.

When we admit the possibility that bonds other than the deliverable issue used in our illustration can be delivered and that it might be advantageous to deliver other issues, the situation becomes somewhat more involved. In this more realistic case, the manager may decide not to deliver this issue, but if she does decide to deliver it, the manager is still assured of receiving an effective sale price of approximately 144.979. If the manager does not deliver this issue, it would be because another issue can be delivered more cheaply, and thus the manager does better than the targeted price.

In summary, if a manager establishes a futures hedge that is held until delivery, the manager can be assured of receiving an effective price dictated by the futures rate (not the spot rate) on the day the hedge is set.

The Target for Hedges with Short Holding Periods. When a manager must lift (remove) a hedge prior to the delivery date, the effective rate that is obtained is much more likely to approximate the current spot rate than the futures rate the shorter the term of the hedge. The critical difference between this hedge and the hedge held to the delivery date is that convergence generally will not take place by the termination date of the hedge.

To illustrate why a manager should expect the hedge to lock in the spot rate rather than the futures rate for very short-lived hedges, let's return to the simplified example used earlier to illustrate a hedge to the delivery date. It is assumed that this issue is the only deliverable Treasury bond for the Treasury bond futures contract. Suppose that the hedge is set three months before the delivery date, and the manager plans to lift the hedge after one day. It is much more likely that the spot price of the bond will move parallel to the converted futures price (i.e., the futures price times the conversion factor) than that the spot price and the converted futures price will converge by the time the hedge is lifted.

A one-day hedge is, admittedly, an extreme example. Other than underwriters, dealers, and traders who reallocate assets very frequently, few money managers are interested in such a short horizon. The very short-term hedge does, however, illustrate a very important point: *when hedging, a manager should not expect to lock in the futures rate (or price) just because he is hedging with futures contracts.* The futures rate is locked in only if the hedge is held until delivery, at which point convergence must take place. If the hedge is held for only one day, the manager should expect to lock in the one-day forward rate,[3] which will very nearly equal the spot rate. Generally, hedges are held for more than one day but not necessarily to delivery.

3. Forward rates are covered in Chapter 36.

How the Basis Affects the Target Rate for a Hedge. The proper target for a hedge that is to be lifted prior to the delivery date depends on the basis. The *basis* is simply the difference between the spot (cash) price of a security and its futures price; that is:

$$\text{Basis} = \text{spot price} - \text{futures price}$$

In the bond market, a problem arises when trying to make practical use of the concept of the basis. The quoted futures price does not equal the price that one receives at delivery. For the Treasury bond and note futures contracts, the actual futures price equals the quoted futures price times the appropriate conversion factor. Consequently, to be useful, the basis in the bond market should be defined using actual futures delivery prices rather than quoted futures prices. Thus the price basis for bonds should be redefined as

$$\text{Price basis} = \text{spot price} - \text{futures delivery price}$$

For hedging purposes, it is also useful frequently to define the basis in terms of interest rates rather than prices. The *rate basis* is defined as

$$\text{Rate basis} = \text{spot rate} - \text{futures rate}$$

where spot rate refers to the current rate on the instrument to be hedged and the futures rate is the interest rate corresponding to the futures delivery price of the deliverable instrument.

The rate basis is helpful in explaining why the two views of hedges explained earlier are expected to lock in such different rates. To see this, we first define the *target rate basis*. This is defined as the expected rate basis on the day the hedge is lifted. A hedge lifted on the delivery date is expected to have, and by convergence will have, a zero rate basis when the hedge is lifted. Thus the target rate for the hedge should be the rate on the futures contract plus the expected rate basis of zero or, in other words, just the futures rate. When a hedge is lifted prior to the delivery date, one would not expect the basis to change very much in one day, so the target rate basis equals the futures rate plus the current difference between the spot rate and futures rate, that is, the current spot rate.

The manager can set the target rate for any hedge equal to the futures rate plus the target rate basis. That is,

$$\text{Target rate for hedge} = \text{futures rate} + \text{target rate basis}$$

If projecting the basis in terms of price rather than rate is more manageable (as is often the case for intermediate- and long-term futures), it is easier to work with the target price basis instead of the target rate basis. The *target price basis* is just the projected price basis for the day the hedge is to be lifted. For a deliverable security, the target for the hedge then becomes

$$\text{Target price for hedge} = \text{futures delivery price} + \text{target price basis}$$

The idea of a target price or rate basis explains why a hedge held until the delivery date locks in a price with certainty, and other hedges do not. The examples

have shown that this is true. For the hedge held to delivery, there is no uncertainty surrounding the target basis; by convergence, the basis on the day the hedge is lifted is certain to be zero. For the short-lived hedge, the basis probably will approximate the current basis when the hedge is lifted, but its actual value is not known. For hedges longer than one day but ending prior to the futures delivery date, there can be considerable basis risk because the basis on the day the hedge is lifted can end up being anywhere within a wide range. Thus the uncertainty surrounding the outcome of a hedge is directly related to the uncertainty surrounding the basis on the day the hedge is lifted (i.e., the uncertainty surrounding the target basis).

The uncertainty about the value of the basis at the time the hedge is removed is called *basis risk*. For a given investment horizon, hedging substitutes basis risk for price risk. Thus one trades the uncertainty of the price of the hedged security for the uncertainty of the basis. Consequently, when hedges do not produce the desired results, it is customary to place the blame on basis risk. However, basis risk is the real culprit only if the target for the hedge is defined properly. Basis risk should refer only to the unexpected or unpredictable part of the relationship between cash and futures prices. The fact that this relationship changes over time does not in itself imply that there is basis risk.

Basis risk, properly defined, refers only to the uncertainty associated with the target rate basis or target price basis. Accordingly, it is imperative that the target basis be defined properly if one is to assess the risk and expected return in a hedge correctly.

Determining the Number of Futures Contracts

The final step that must be determined before the hedge is set is the number of futures contracts needed for the hedge. This is called the *hedge ratio*. Usually the hedge ratio is expressed in terms of relative par amounts. Accordingly, a hedge ratio of 1.20 means that for every $1 million par value of securities to be hedged, one needs $1.2 million par value of futures contracts to offset the risk. *In our discussion, the values are defined so that the hedge ratio is the number of futures contracts.*

Earlier we defined a cross-hedge in the futures market as a hedge in which the security to be hedged is not deliverable on the futures contract used in the hedge. For example, a manager who wants to hedge the sale price of long-term corporate bonds might hedge with the Treasury bond futures contract, but since non-Treasury bonds cannot be delivered in satisfaction of the contract, the hedge would be considered a cross-hedge. A manger also might want to hedge a rate that is of the same quality as the rate specified in one of the contracts but that has a different maturity. For example, it is necessary to cross-hedge a Treasury bond, note, or bill with a maturity that does not qualify for delivery on any futures contract. Thus, when the security to be hedged differs from the futures contract specification in terms of either quality or maturity, one is led to the cross-hedge.

Conceptually, cross-hedging is somewhat more complicated than hedging deliverable securities because it involves two relationships. First, there is the relationship between the cheapest-to-deliver (CTD) issue and the futures contract.

Second, there is the relationship between the security to be hedged and the CTD. Practical considerations at times may lead a manager to shortcut this two-step relationship and focus directly on the relationship between the security to be hedged and the futures contract, thus ignoring the CTD altogether. However, in so doing, a manager runs the risk of miscalculating the target rate and the risk in the hedge. Furthermore, if the hedge does not perform as expected, the shortcut makes it difficult to tell why the hedge did not work out as expected.

The key to minimizing risk in a cross-hedge is to choose the right number of futures contracts. This depends on the relative dollar duration of the bond to be hedged and the futures position. Equation (61–4) indicated the number of futures contracts to achieve a particular target dollar duration. The objective in hedging is to make the target dollar duration equal to zero. Substituting zero for target dollar duration in Eq. (61–4) we obtain

$$\text{Number of futures contracts} = -\frac{\text{current dollar duration without futures}}{\text{dollar duration per futures contract}} \qquad (61\text{–}5)$$

To calculate the dollar duration of a bond, the manager must know the precise point in time that the dollar duration is to be calculated (because volatility generally declines as a bond matures), as well as the price or yield at which to calculate dollar duration (because higher yields generally reduce dollar duration for a given yield change). The relevant point in the life of the bond for calculating volatility is the point at which the hedge will be lifted. Dollar duration at any other point is essentially irrelevant because the goal is to lock in a price or rate only on that particular day. Similarly, the relevant yield at which to calculate dollar duration initially is the target yield. Consequently, the numerator of Eq. (61–5) is the dollar duration on the date the hedge is expected to be delivered. The yield that is to be used on this date in order to determine the dollar duration is the forward rate.

Let's look at how we apply Eq. (61–5) when using the Treasury bond futures contract to hedge. The number of futures contracts will be affected by the dollar duration of the CTD issue. We can modify Eq. (61–5) as follows:

$$\text{Number of futures contracts} = -\frac{\text{current dollar duration without futures}}{\text{dollar duration of the CTD issue}} \times \frac{\text{dollar duration of the CTD issue}}{\text{dollar duration per futures contract}} \qquad (61\text{–}6)$$

As noted earlier, the conversion ratio for the CTD issue is a good approximation of the second ratio. Thus Eq. (61–6) can be rewritten as

$$\text{Number of futures contracts} = -\frac{\text{current dollar duration without futures}}{\text{dollar duration of the CTD issues}} \times \text{conversion factor for the CTD issue} \qquad (61\text{–}7)$$

An Illustration. An example for a single bond shows why dollar duration weighting leads to the correct number of contracts to use to hedge. The hedge illustrated is a cross-hedge. Suppose that on 6/24/99 a manager owned $10 million par value of a 6.25% Fannie Mae (FNMA) option-free bond maturing on 5/15/29 selling at 88.39 to yield 7.20%. The manager wants to sell September 1999 Treasury bond futures to hedge a future sale of the FNMA bond. At the time, the price of the September Treasury bond futures contract was at 113. The CTD issue was the 11.25% of 2/15/15 issue that was trading at the time at 146.19 to yield 6.50%. The conversion factor for the CTD issue was 1.283. To simplify, assume that the yield spread between the FNMA bond and the CTD issue remains at 0.70% (i.e., 70 basis points) and that the anticipated sale date is the last business day in September 1999.

The target price for hedging the CTD issue would be 144.979 (from 113 × 1.283), and the target yield would be 6.56% (the yield at a price of 144.979). Since the yield on the FNMA bond is assumed to stay at 0.70% above the yield on the CTD issue, the target yield for the FNMA bond would be 7.26%. The corresponding price for the FNMA bond for this target yield is 87.76. At these target levels, the dollar duration for a 50 basis point change in rates for the CTD issue and FNMA bond per $100 of par value is $6.255 and $5.453, respectively. As indicated earlier, all these calculations are made using a settlement date equal to the anticipated sale date, in this case the end of September 1999. The dollar duration for $10 million par value of the FNMA bond is then $545,300 ($10 million/100 times $5.453). Per $100,000 par value for the CTD issue, the dollar duration per futures contract is $6,255 ($100,000/100 times $6.255).

Thus we know

$$\begin{aligned}\text{Current dollar duration without futures}\\ &= \text{dollar duration of the FNMA bond}\\ &= \$545{,}300\\ \text{Dollar duration of the CTD issue} &= \$6{,}255\\ \text{Conversion factor for CTD issue} &= 1.283\end{aligned}$$

Substituting these values into Eq. (61–7), we obtain

$$\text{Number of futures contracts} = \frac{\$545{,}300}{\$6{,}255} \times 1.283 = -112 \text{ contracts}$$

Consequently, to hedge the FNMA bond position, 112 Treasury bond futures contracts must be shorted.

Exhibit 61–2 uses scenario analysis to show the outcome of the hedge based on different prices for the FNMA bond at the delivery date of the futures contract. Let's go through each of the columns. Column (1) shows the assumed sale price for the FNMA bond, and column (2) shows the corresponding yield based on the actual sale price in column (1). This yield is found from the

EXHIBIT 61–2

Hedging a Nondeliverable Bond to a Delivery Date with Futures

Instrument to be hedged: $10 million FNMA 6.25% of 05/15/29
Price of FNMA as of hedge date (6/24/99) = 88.39
Conversion factor for September 1999 = 1.283
Price of futures contract when sold = 113
Target price for FNMA bonds = 87.76
Par value hedged = $10,000,000
Number of futures contracts = 112
Futures position = $12,656,000
Target market value for FNMA bonds = $8,776,000

(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)
Actual Sale Price of FNMA Bonds	Yield at Sale	Yield of 11.25% Treasury Bond*	Price of 11.25% Treasury Bond	Futures Price†	Value of Futures Position	Gain or Loss on Futures Position	Effective Sale Price‡

*By assumption, the yield on the cheapest-to-deliver issue is 70 basis points lower than the yield on the FNMA bond.
†By convergence, the futures price equals the price of the cheapest-to-deliver issue divided by 1.283 (the conversion factor).
‡Transaction costs and the financing of margin flows are ignored.

price/yield relationship. Given the assumed sale price for the FNMA bond, the corresponding yield can be determined. Column (3) shows the yield for the CTD issue. This yield is computed based on the assumption regarding the yield spread of 70 basis points between the FNMA bond and the CTD issue. Thus, by subtracting 70 basis points from the yield for the FNMA bond in column (2), the yield on

the CTD issue (the 11.25% of 2/15/15) is obtained. Given the yield for the CTD issue in column (3), the price per $100 of par value of the CTD issue can be computed. This CTD price is shown in column (4).

Now we must move from the price of the CTD issue to the futures price. As explained in the description of the columns in Exhibit 61–1, by dividing the price for the CTD issue shown in column (4) by the conversion factor of the CTD issue (1.283), the futures price is obtained. This price is shown in column (5).

The value of the futures position is found in the same way as in Exhibit 61–1. First, the futures price per $1 of par value is computed by dividing the futures price by 100. Then this value is multiplied by $100,000 (the par value for the contract) and the number of futures contracts. That is,

Value of futures position

$$= (\text{futures price}/100) \times \$100,0000 \times \text{number of futures contracts}$$

Since the number of futures contracts sold is 112,

$$\text{Value of futures position} = (\text{final futures price}/100) \times \$100,0000 \times 112$$

The values shown in column (6) use the preceding formula. Using the first assumed actual sale price for the FNMA of $8 million as an example, the corresponding futures price in column (5) is 105.85581. Therefore, the value of the futures position is

$$\begin{aligned}\text{Value of futures position} &= (105.85581/100) \times \$100,000 \times 112\\ &= \$11,855,850\end{aligned}$$

Now let's calculate the gain or loss on the futures position shown in column (7). This is done in the same manner as explained for Exhibit 61–1. Since the futures price at which the contracts are sold at the inception of the hedge is 113, the gain or loss on the futures position is found as follows:

$$(113/100 - \text{final futures price}/100) \times \$100,000 \times \text{number of futures contracts}$$

For example, for the first scenario in Exhibit 61–2, the futures price is 105.85581, and 112 futures contract were sold. Therefore,

$$(113/100 - 105.85581/100) \times \$100,000 \times 112 = \$800,150$$

There is a gain from the futures position because the futures price is less than 113. Note that for all the final futures prices above 113 in Exhibit 61–2, there is a negative value, which means that there is a loss on the futures position. For all futures prices below 113, there is a loss.

Finally, column (8) shows the effective sale price for the FNMA bond. This value is found as follows:

Effective sale price for FNMA bond

= actual sale price of FNMA bond + gain or loss on futures position

For the actual sale price of $8 million, the gain is $800,150. Therefore, the effective sale price for the FNMA bond is

$$\$8{,}000{,}000 + \$800{,}150 = \$8{,}800{,}150$$

Looking at column (8) of Exhibit 61–2, we see that if the simplifying assumptions hold, a futures hedge using the recommended number of futures contracts (112) very nearly locks in the target price for $10 million par value of the FNMA bonds.

Refining for Changing Yield Spread. Another refinement in the hedging strategy is usually necessary for hedging nondeliverable securities. This refinement concerns the assumption about the relative yield spread between the CTD issue and the bond to be hedged. In the prior discussion, we assumed that the yield spread was constant over time. Yield spreads, however, are not constant over time. They vary with the maturity of the instruments in question and the level of rates, as well as with many unpredictable and nonsystematic factors.

Regression analysis allows the manager to capture the relationship between yield levels and yield spreads and use it to advantage. For hedging purposes, the variables are the yield on the bond to be hedged and the yield on the CTD issue. The regression equation takes the form

$$\text{Yield on bond to be hedged} = a + b \times \text{yield on CTD issue} + \text{error} \qquad (61\text{–}8)$$

The regression procedure provides an estimate of b, which is the expected relative yield change in the two bonds. This parameter b is called the *yield beta*. Our example that used constant spreads implicitly assumes that the yield beta b equals 1.0 and a equals 0.70 (because 0.70 is the assumed spread).

For the two issues in question, that is, the FNMA bond and the CTD issue, suppose that the estimated yield beta was 1.05. Thus yields on the FNMA issue are expected to move 5% more than yields on the Treasury issue. To calculate the number of futures contracts correctly, this fact must be taken into account; thus the number of futures contracts derived in our earlier example is multiplied by the factor 1.05. Consequently, instead of shorting 112 Treasury bond futures contracts to hedge $10 million of the FNMA bond, the investor would short 118 (rounded up) contracts.

The formula for the number of futures contracts is revised as follows to incorporate the impact of the yield beta:

$$\begin{aligned}\text{Number of futures contracts} = &-\frac{\text{current dollar duration without futures}}{\text{dollar duration of the CTD issue}}\\ &\times \text{conversion factor for the CTD issue}\\ &\times \text{yield beta} \qquad (61\text{–}9)\end{aligned}$$

where the yield beta is derived from the yield of the bond to be hedged regressed on the yield of the CTD issue (Eq. 61–8).

The effect of a change in the CTD issue and the yield spread can be assessed before the hedge is implemented. An exhibit similar to that of Exhibit 61–2 can be constructed under a wide range of assumptions. For example, at different yield levels at the date the hedge is to be lifted (the second column in Exhibit 61–2), a different yield spread may be appropriate and a different acceptable issue will be the CTD issue. The manager can determine what this will do to the outcome of the hedge.

Monitoring and Evaluating the Hedge

After a target is determined and a hedge is set, there are two remaining tasks. The hedge must be monitored during its life and evaluated after it is over. Most futures hedges require very little active monitoring during their life. In fact, overactive management poses more of a threat to most hedges than does inactive management. The reason for this is that the manager usually will not receive enough new information during the life of the hedge to justify a change in the hedging strategy. For example, it is not advisable to readjust the hedge ratio every day in response to a new data point and a possible corresponding change in the estimated value of the yield beta.

There are, however, exceptions to this general rule. As rates change, dollar duration changes. Consequently, the hedge ratio may change slightly. In other cases, there may be sound economic reasons to believe that the yield beta has changed. While there are exceptions, the best approach is usually to let a hedge run its course using the original hedge ratio with only slight adjustments.

A hedge normally can be evaluated only after it has been lifted. Evaluation involves, first, an assessment of how closely the hedge locked in the target rate—that is, how much error there was in the hedge. To provide a meaningful interpretation of the error, the manager should calculate how far from the target the sale (or purchase) would have been had there been no hedge at all. One good reason for evaluating a completed hedge is to ascertain the sources of error in the hedge in the hope that the manager will gain insights that can be used to advantage in subsequent hedges. A manager will find that there are three major sources of hedging errors:

1. The dollar duration for the hedged instrument was incorrect.
2. The projected value of the basis at the date the hedge is removed can be in error.
3. The parameters estimated from the regression (a and b) can be inaccurate.

Recall from the calculation of duration in Chapter 7 that interest rates are changed up and down by a small number of basis points and the security is revalued. The two recalculated values are used in the numerator of the duration formula. The first problem just listed recognizes that the instrument to be hedged may be a complex instrument (i.e., one with embedded options) and that the valuation model does not do a good job of valuing the security when interest rates change.

The second major source of errors in a hedge—an inaccurate projected value of the basis—is the more difficult problem. Unfortunately, there are no satisfactory simple models like regression that can be applied to the basis. Simple models of the basis violate certain equilibrium relationships for bonds that should not be violated. On the other hand, theoretically rigorous models are very unintuitive and usually soluble only by complex numerical methods. Modeling the basis is undoubtedly one of the most important and difficult problems that managers seeking to hedge face.

HEDGING WITH OPTIONS

Hedging strategies using options involve taking a position in an option and a position in the underlying bond in such a way that changes in the value of one position will offset any unfavorable price (interest rate) movement in the other position. We begin with the basic hedging strategies using options. Then we illustrate these basic strategies using futures options to hedge the FNMA bond for which a futures hedge was used earlier in this chapter. Using futures options in our illustration of hedging the bond is a worthwhile exercise because it shows how complicated hedging with futures options is and the key parameters involved in the process. We also compare the outcome of hedging with futures and hedging with futures options.

Basic Hedging Strategies

There are three popular hedging strategies: (1) a protective put-buying strategy, (2) a covered call-writing strategy, and (3) a collar strategy. We discuss each strategy below.

Protective Put-Buying Strategy

Consider a manager who has a bond and wants to hedge against rising interest rates. The most obvious options hedging strategy is to buy put options on bonds. This hedging strategy is referred to as a *protective put-buying strategy*. The puts are usually out-of-the-money puts and may be either puts on cash bonds or puts on interest-rate futures. If interest rates rise, the puts will increase in value (holding other factors constant), offsetting some or all of the loss on the bonds in the portfolio.

This strategy is a simple combination of a long put option with a long position in a cash bond. Such a position has limited downside risk, but large upside potential. However, if rates fall, the price appreciation on the bonds in the portfolio will be diminished by the amount paid to purchase the puts. Exhibit 61–3 compares the protective put-buying strategy to an unhedged position.

The protective put-buying strategy is very often compared with purchasing insurance. Like insurance, the premium paid for the protection is nonrefundable

EXHIBIT 61–3

Protective Put-Buying Strategy

and is paid before the coverage begins. The degree to which a portfolio is protected depends on the strike price of the options; thus the strike price is often compared with the deductible on an insurance policy. The lower the deductible (i.e., the higher the strike price for the put), the greater is the level of protection, and the more the protection costs. Conversely, the higher the deductible (the lower the strike price on the put), the more the portfolio can lose in value, but the cost of the insurance is lower. Exhibit 61–4 compares an unhedged position with several protective put positions, each with a different strike price, or level of protection. As the exhibit shows, no one strategy dominates any other strategy, in the sense of performing better at all possible rate levels. Consequently, it is impossible to say that one strike price is necessarily the "best" strike price or even that buying protective puts is necessarily better than doing nothing at all.

Covered Call-Writing Strategy

Another options hedging strategy used by many portfolio managers is to sell calls against the bond portfolio. This hedging strategy is called a *covered call-writing strategy.* The calls that are sold are usually out-of-the-money calls and can be either calls on cash bonds or calls on interest-rate futures. Covered call writing is just an outright long position combined with a short call position. Obviously, this strategy entails much more downside risk than buying a put to protect the value

EXHIBIT 61–4

Protective Put-Buying Strategy with Different Strike Prices

of the portfolio. In fact, many portfolio managers do not consider covered call writing a hedge.

Regardless of how it is classified, it is important to recognize that while covered call writing has substantial downside risk, it has less downside risk than an unhedged long position alone. On the downside, the difference between the long position alone and the covered call-writing strategy is the premium received for the calls that are sold. This premium acts as a cushion for downward movements in prices, reducing losses when rates rise. The cost of obtaining this cushion is that the manager gives up some of the potential on the upside. When rates decline, the call options become greater liabilities for the covered call writer. These incremental liabilities decrease the gains the manager would otherwise have realized on the portfolio in a declining rate environment. Thus the covered call writer gives up some (or all) of the upside potential of the portfolio in return for a cushion on the downside. The more upside potential that is forfeited (i.e., the lower the strike price on the calls), the more cushion there is on the downside. Exhibit 61–5 illustrates this point by comparing an unhedged position to several covered call-writing strategies, each with a different strike price. Like the protective put-buying strategy, there is no "right" strike price for the covered call writer.

EXHIBIT 61–5

Covered Call-Writing Strategy with Different Strike Prices

Collar Strategy

There are other hedging strategies employing options that are used frequently by managers. For example, many managers combine the protective put-buying strategy and the covered call-writing strategy. By combining a long position in an out-of-the-money put and a short position in an out-of-the-money call, the manager creates a long position in a *collar*. Consequently, this hedging strategy is called a *collar strategy*. The manager who uses the collar eliminates part of the portfolio's downside risk by giving up part of its upside potential. A long position hedged with a collar is shown in Exhibit 61–6.

The collar in some ways resembles the protective put, in some ways resembles covered call writing, and in some ways resembles an unhedged position. The collar is like the protective put-buying strategy in that it limits the possible losses on the portfolio if interest rates go up. Like the covered call-writing strategy, the portfolio's upside potential is limited. Like an unhedged position, within the range defined by the strike prices, the value of the portfolio varies with interest rates.

Selecting the "Best" Strategy

Comparing the two basic strategies for hedging with options, one cannot say that the protective put-buying strategy or the covered call-writing strategy is necessarily

EXHIBIT 61–6

Long Position Hedged with a Collar

the better or more correct options hedge. The best strategy (and the best strike price) depends on the manager's view of the market. Purchasing a put and paying the required premium are appropriate if the manager is fundamentally bearish. If, instead, the manager is neutral to mildly bearish, it is better to receive the premium on the covered call-writing strategy. If the manager prefers to take no view on the market at all, and as little risk as possible, then the futures hedge is the most appropriate. If the manager is fundamentally bullish, then no hedge at all is probably the best strategy.

Steps in Options Hedging

Like hedging with futures, there are steps that managers should consider before setting their hedges. These steps include

Step 1. Determine the option contract that is the best hedging vehicle. The best option contract to use depends on several factors. These include option price, liquidity, and correlation with the bond(s) to be hedged. In price-inefficient markets, the option price is important because not all options will be priced in the same manner or with the same volatility assumption. Consequently, some options may be overpriced and some underpriced. Obviously, with other factors equal, it is better to use the underpriced options when buying and the overpriced options when selling.

Whenever there is a possibility that the option position may be closed out prior to expiration, liquidity is also an important consideration. If the particular option is illiquid, closing out a position may be prohibitively expensive, and the manager loses the flexibility of closing out positions early or rolling into other positions that may become more attractive. Correlation with the underlying bond(s) to be hedged is another factor in selecting the right contract. The higher the correlation, the more precisely the final profit and loss can be defined as a function of the final level of rates. Poor correlation leads to more uncertainty.

While most of the uncertainty in an options hedge usually comes from the uncertainty of interest rates themselves, the degree of correlation between the bonds to be hedged and the instruments underlying the options contracts add to that risk. The lower the correlation, the greater the risk.

Step 2. Find the appropriate strike price. For a cross-hedge, the manager will want to convert the strike price on the options that are actually bought or sold into an equivalent strike price for the actual bonds being hedged.

Step 3. Determine the number of contracts. The hedge ratio is the number of options to buy or sell.

Steps 2 and 3, determining the strike price and the number of contracts, can best be explained with examples using futures options.

Protective Put-Buying Strategy Using Futures Options

As explained earlier, managers who want to hedge their bond positions against a possible increase in interest rates will find that buying puts on futures is one of the easiest ways to purchase protection against rising rates. To illustrate a protective put-buying strategy, we can use the same FNMA bond that we used to demonstrate how to hedge with Treasury bond futures.[4] In that example, a manager held $10 million par value of a 6.25% FNMA bond maturing 5/15/29 and used September 1999 Treasury bond futures to lock in a sale price for those bonds on the futures delivery date. Now we want to show how the manager could use futures options instead of futures to protect against rising rates.

4. As explained in Chapter 59, futures options on Treasury bonds are used more commonly by institutional investors. The mechanics of futures options are as follows: If a put option is exercised, the option buyer receives a short position in the underlying futures contract and the option writer receives the corresponding long position. The futures price for both positions is the strike price for the put option. The exchange then marks the positions to market and the futures price for both positions is then the current futures price. If a call option is exercised, the option buyer receives a long position in the underlying futures contract and the option writer receives the corresponding short position. The futures price for both positions is the strike price for the call option. The exchange then marks the positions to market and the futures price for both positions is then the current futures price.

On 6/24/99, the FNMA bond was selling for 88.39 to yield 7.20%, and the CTD issue's yield was 6.50%. For simplicity, it is assumed that the yield spread between the FNMA bond and the CTD issue remains at 70 basis points.

Selecting the Strike Price

The manager must determine the minimum price that he wants to establish for the FNMA bonds. In our illustration, we will assume that the minimum price before the cost of the put options purchased is 84.453. This is equivalent to saying that the manager wants to establish a strike price for a put option on the hedged bonds of 84.453. But the manager is not buying a put option on the FNMA bond. He is buying a put option on a Treasury bond futures contract. Therefore, the manager must determine the strike price for a put option on a Treasury bond futures contract that is equivalent to a strike price of 84.453 for the FNMA bond.

This can be done with the help of Exhibit 61–7. We begin at the top left-hand box of the exhibit. Since the minimum price is 84.453 for the FNMA bond, this means that the manager is attempting to establish a maximum yield of 7.573%. This is found from the relationship between price and yield: given a price of 84.453 for the FNMA bond, this equates to a yield of 7.573%. (This gets us to the lower left-hand box in Exhibit 61–7.) From the assumption that the spread between the FNMA bond and the cheapest-to-deliver issue is a constant 70 basis points, setting a maximum yield of 7.573% for the FNMA bond is equivalent to setting a maximum yield of 6.873% for the cheapest-to-deliver issue. (Now we are at the lower box in the middle column of Exhibit 61–7.) Given the yield of 6.873% for the CTD issue, the minimum price before the cost of the puts purchased can be determined (the top box in the middle column of the

EXHIBIT 61–7

Calculating Equivalent Strike Prices and Yields for Hedging with Futures Options

exhibit). A 6.873% yield for the CTD issue gives us a price of 141.136. (This is determined from the characteristics of the CTD issue.) The corresponding futures price is found by dividing the price of the CTD issue by the conversion factor. This gets us to the box in the right-hand column of Exhibit 61–7. Since the conversion factor is 1.283, the futures price is about 110 (141.136 divided by 1.283). This means that a strike price of 110 for a put option on a Treasury bond futures contract is roughly equivalent to a put option on our FNMA bond with a strike price of 84.453.

The foregoing steps are always necessary to obtain the appropriate strike price on a put futures option. The process is not complicated. It simply involves (1) the relationship between price and yield, (2) the assumed relationship between the yield spread between the bonds to be hedged and the cheapest-to-deliver issue, and (3) the conversion factor for the cheapest-to-deliver issue. As with hedging employing futures illustrated earlier in this chapter, the success of the hedging strategy will depend on (1) whether the cheapest-to-deliver issue changes and (2) the yield spread between the bonds to be hedged and the cheapest-to-deliver issue.

Calculating the Number of Options Contracts

The hedge ratio is determined using the following equation similar to Eq. (61–7) because we will assume a constant yield spread between the bond to be hedged and the cheapest-to-deliver issue:

$$\text{Number of options contracts} = \frac{\text{current dollar duration without options}}{\text{dollar duration of the CTD issue}} \times \text{conversion factor for CTD issue}$$

The dollar durations are as follows per 50 basis point change in rates:

Current dollar duration without options = \$512,320

Dollar duration of the CTD issue = \$6,021

Notice that the dollar durations are different from those used in calculating the number of futures contracts for the futures hedge. This is so because the dollar durations are calculated at prices corresponding to the strike price of the futures option (110) rather than the futures price (113). The number of futures options contracts is then

$$\text{Number of options contracts} = \frac{\$512,320}{\$6,021} \times 1.283 = 109 \text{ put options}$$

Thus, to hedge the FNMA bond position with put options on Treasury bond futures, 109 put options must be purchased.

Outcome of the Hedge

To create a table for the protective put hedge, we can use some of the numbers from Exhibit 61–2. Exhibit 61–8 shows the scenario analysis for the protective

EXHIBIT 61–8

Hedging a Nondeliverable Bond to a Delivery Date with Puts on Futures

Instrument to be hedged: $10 million FNMA 6.25% of 05/15/29
Price of FNMA as of hedge date (6/24/99) = 88.39
Conversion factor for September 1999 = 1.283
Price of futures contract when sold = 113
Target price per bond for FNMA bonds = 84.453
Effective minimum sale price = 83.908
Par value hedged = $10,000,000
Strike price for put = 110
Number of puts on futures = 109
Price per contract = $500.00
Cost of put position = $54,500

9,500,000	6.637	5.937	153.078	119.31255	0	54,500	9,445,500

*These numbers are approximate because futures trade in 32nds.
†From maximum of [(110/100 – futures price/100) × $100,000 × 109, 0].
‡Does not include transaction costs or the financing of the options position.

put-buying strategy. The first five columns are the same as in Exhibit 61–2. For the put option hedge, column (6) shows the value of the put option position at the expiration date. The value of the put option position at the expiration date will be equal to zero if the futures price is greater than or equal to the strike price of 110.

If the futures price is below 110, then the options expire in the money, and the value of the put option position is

Value of put option position

$$= (110/100 - \text{futures price}/100) \times \$100{,}000 \times \text{number of put options}$$

For example, for the first scenario in Exhibit 61–8 of $8 million for the actual sale price of the FNMA bond, the corresponding futures price is 105.85581. The number of put options purchased is 109. Therefore

$$(110/100 - 105.85581/100) \times \$100{,}000 \times 109 = \$45{,}717$$

The effective sale price for the FNMA bonds is then equal to

Effective sale price = actual sale price + value of put option position
– option cost

Let's look at the option cost. Suppose that the price of the put option with a strike price of 110 is $500 per contract. With a total of 109 options, the cost of the protection is $54,500 (109 × $500, not including financing costs and commissions). This cost is shown in column (7) and is equivalent to 0.545 per $100 par value hedged.

The effective sale price for the FNMA bonds for each scenario is shown in the last column of Exhibit 61–8. This effective sale price is never less than 83.908. This equals the price of the FNMA bonds equivalent to the futures strike price of 110 (i.e., 84.453) minus the cost of the puts (i.e., 0.545 per $100 par value hedged). This minimum effective price is something that can be calculated before the hedge is ever initiated. (As prices decline, the effective sale price actually exceeds the target minimum sale price of 83.908 by a small amount. This is due only to rounding and the fact that the hedge ratio is left unaltered, although the relative dollar durations that go into the hedge ratio calculation change as yields change.) As prices increase, however, the effective sale price of the hedged bonds increases as well; unlike the futures hedge shown in Exhibit 61–2, the options hedge protects the investor if rates rise but allows the investor to profit if rates fall.

Covered Call-Writing Strategy with Futures Options

Unlike the protective put-buying strategy, covered call writing is not entered into with the sole purpose of protecting a portfolio against rising rates. The covered call writer, believing that the market will not trade much higher or much lower than its present level, sells out-of-the-money calls against an existing bond portfolio. The sale of the calls brings in premium income that provides partial protection in case rates increase. The premium received does not, of course, provide the kind of protection that a long put position provides, but it does provide some additional income that can be used to offset declining prices. If, instead, rates fall, portfolio appreciation is limited because the short call position constitutes a

liability for the seller, and this liability increases as rates decline. Consequently, there is limited upside price potential for the covered call writer. Of course, this is not so bad if prices are essentially going nowhere; the added income from the sale of call options is obtained without sacrificing any gains.

To see how covered call writing with futures options works for the bond used in the protective put example, we construct a table much as we did before. With futures selling around 113 on the hedge initiation date, a sale of a 117 call option on futures might be appropriate. As before, it is assumed that the hedged bond will remain at a 70 basis point spread over the CTD issue. We also assume for simplicity that the price of the 117 calls is $500 per contract. The number of options contracts sold will be the same, namely, 109 contracts for $10 million face value of underlying bonds. Thus, the proceeds received from the sale of the 109 call options is $54,500 (109 contracts × $500) or 0.545 per $100 par value hedged.

Exhibit 61–9 shows the outcomes of the covered call-writing strategy given these assumptions. The first five columns of the exhibit are the same as for Exhibit 61–8. In column (6), the liability resulting from the call option position is shown. The liability is zero if the futures price for the scenario is less than the strike price of 117. If the futures price for the scenario is greater than 117, the liability is calculated as follows:

$$(\text{Futures price}/100 - 117/100) \times \$100{,}000 \times \text{number of put options}$$

For example, consider the scenario in Exhibit 61–9, where the actual sale price of the FNMA bond is $9.5 million. The corresponding futures price is 119.31255. The number of call options sold is 109. Therefore

$$(119.31255/100 - 117/100) \times \$100{,}000 \times 109 = \$252{,}068$$

That is,

$$\begin{aligned}\text{Effective sale price} = {} & \text{actual sale price} \\ & + \text{proceeds from sale of the call options} \\ & - \text{liability of call position}\end{aligned}$$

Since the proceeds from sale of the call options is $54,500, then

$$\text{Effective sale price} = \text{actual sale price} + \$54{,}000 - \text{liability of call position}$$

The last column of Exhibit 61–9 shows the effective sale price for each scenario.

Just as the minimum effective sale price could be calculated beforehand for the protective put-buying strategy, the maximum effective sale price can be calculated beforehand for the covered call-writing strategy. The maximum effective sale price will be the price of the hedged bond corresponding to the strike price of the option sold plus the premium received. In this case, the strike price on the futures call option is 117. A futures price of 117 corresponds to a price of 150.111 (from 117 times the conversion factor of 1.283) and a corresponding

EXHIBIT 61–9

Writing Calls on Futures against a Nondeliverable Bond

‡Does not include transaction costs or interest on the option premium received.

yield of 6.159% for the cheapest-to-deliver issue. The equivalent yield for the hedged bond is 70 basis points higher, or 6.859%, for a corresponding price of 92.313. Adding on the premium received of 0.545 per $100 par value hedged, the final maximum effective sale price will be about 92.858. As Exhibit 61–10 shows, if the hedged bond does trade at 70 basis points over the CTD issue as

EXHIBIT 61–10

Comparison of Alternative Strategies

(1) Actual Sale Price of FNMA Bonds	(2) Effective Sale Price with Futures Hedge	(3) Effective Sale Price with Protective Puts	(4) Effective Sale Price with Covered Calls
8,000,000	8,800,150	8,397,217	8,054,500
8,100,000	8.793,824	8,393,739	8,154,500
8,200,000	8,788,807	8,391,536	8,254,500
8,300,000	8.785,101	8,390,607	8,354,500
8,400,000	8,781,481	8,389,763	8,454,500
8,500,000	8,779,171	8,445,500	8,554,500
8,600,000	8,778,170	8,545,500	8,654,500
8,700,000	8,777,256	8,645,500	8,754,500
8,800,000	8,776,343	8,745,500	8,854,500
8,900,000	8.776,739	8,845,500	9,954,500
9,000,000	8,777,222	8,945,500	9,054,500
9,100,000	8,779,015	9,045,500	9,154,500
9,200,000	8,782,117	9,145,500	9,254,500
9,300,000	8,785,306	9,245,500	9,289,593
9,400,000	8,788,496	9,345,500	9,295,375
9,500,000	8,792,995	9,445,500	9,302,432

assumed, the maximum effective sale price for the hedged bond is, in fact, slightly over 92.858. The discrepancies shown in the exhibit are due to rounding and the fact that the position is not adjusted even though the relative dollar durations change as yields change.

Comparing Alternative Strategies

In this chapter we reviewed three basic strategies for hedging a bond position: (1) hedging with futures, (2) hedging with out-of-the-money puts, and (3) covered call writing with out-of-the-money calls. Similar but opposite strategies exist for managers who are concerned that rates will decrease. As might be expected, there is no "best" strategy. Each strategy has its advantages and its disadvantages, and we never get something for nothing. To get anything of value, something else of value must be forfeited.

To make a choice among strategies, it helps to lay the alternatives side by side. Using the futures example and the futures options examples, Exhibit 61–10 shows the final values of the portfolio for the various hedging alternatives. It is

easy to see from Exhibit 61–10 that if one alternative is superior to another alternative at one level of rates, it will be inferior at some other level of rates.

Consequently, we cannot conclude that one strategy is the best strategy. The manager who makes the strategy decision makes a choice among probability distributions, not usually among specific outcomes. Except for the perfect hedge, there is always some range of possible final values of the portfolio. Of course, exactly what that range is, and the probabilities associated with each possible outcome, is a matter of opinion.

Hedging with Options on Cash Instruments

Hedging a position with options on cash bonds is relatively straightforward. Most strategies, including the purchase of protective puts, covered call writing, and buying collars, are essentially the same whether futures options or options on physicals are used. There are some mechanical differences in the way the two types of option contracts are traded, and there may be substantial differences in their liquidity. Nonetheless, the basic economics of the strategies are virtually identical.

Using options on physicals frequently relieves the manager of much of the basis risk associated with a futures options hedge. For example, a manager of Treasury bonds or notes usually can buy or sell options on the exact security held in the portfolio. Using options on futures, rather than options on Treasury bonds, is sure to introduce additional elements of uncertainty.

Given the illustration presented earlier, and given that the economics of options on physicals and options on futures are essentially identical, additional illustrations for options on physicals are unnecessary. The only important difference is the hedge ratio calculation and the calculation of the equivalent strike price. To derive the hedge ratio, we always resort to an expression of relative dollar durations. Thus, for options on physicals assuming a constant spread, the hedge ratio is

$$\frac{\text{Current dollar duration without options}}{\text{Dollar duration of underlying for option}}$$

If a relationship is estimated between the yield on the bonds to be hedged and the instrument underlying the option, the appropriate hedge ratio is

$$\frac{\text{Current dollar duration without options}}{\text{Dollar duration of underlying for option}} \times \text{yield beta}$$

Unlike futures options, there is only one deliverable, so there is no conversion factor. When cross-hedging with options on physicals, the procedure for finding the equivalent strike price on the bonds to be hedged is very similar. Given the strike price of the option, the strike yield is easily determined using the price/yield relationship for the instrument underlying the option. Then, given the projected relationship between the yield on the instrument underlying the option

and the yield on the bonds to be hedged, an equivalent strike yield is derived for the bonds to be hedged. Finally, using the yield-to-price formula for the bonds to be hedged, the equivalent strike price for the bonds to be hedged can be found.

KEY POINTS

- Buying an interest-rate futures contract increases a portfolio's duration; selling an interest-rate futures contract decreases a portfolio's duration.
- The advantages of adjusting a portfolio's duration using futures rather than cash-market instruments are that transaction costs are lower, margin requirements are lower, and short selling in the futures market is easier.
- The general principle in controlling interest-rate risk with futures is to combine the dollar exposure of the current portfolio and that of a futures position so that it is equal to the target dollar exposure. The number of futures contracts needed to achieve the target dollar duration depends on the current dollar duration of the portfolio without futures and the dollar duration per futures contract.
- Hedging with futures calls for taking a futures position as a temporary substitute for transactions to be made in the cash market at a later date, with the expectation that any loss realized by the manager from one position (whether cash or futures) will be offset by a profit on the other position.
- Hedging is a special case of controlling interest-rate risk in which the target duration or target dollar duration is zero.
- Cross-hedging occurs when the bond to be hedged is not identical to the bond underlying the futures contract. A short or sell hedge is used to protect against a decline in the cash price of a bond; a long or buy hedge is employed to protect against an increase in the cash price of a bond.
- The steps in hedging include (1) determining the appropriate hedging instrument, (2) determining the target for the hedge, (3) determining the position to be taken in the hedging instrument, and (4) monitoring and evaluating the hedge.
- The key factor to determine which futures contract will provide the best hedge is the degree of correlation between the rate on the futures contract and the interest rate that creates the underlying risk that the manager seeks to eliminate.
- The manager should determine the target rate or target price, which is what is expected from the hedge. The hedge ratio is the number of futures contracts needed for the hedge.

- The basis is the difference between the spot price (or rate) and the futures price (or rate).
- In general, when hedging to the delivery date of the futures contract, a manager locks in the futures rate or price. Hedging with Treasury bond futures and Treasury note futures is complicated by the delivery options embedded in these contracts. When a hedge is lifted prior to the delivery date, the effective rate (or price) that is obtained is much more likely to approximate the current spot rate than the futures rate the shorter the term of the hedge.
- The proper target for a hedge that is to be lifted prior to the delivery date depends on the basis. Basis risk refers only to the uncertainty associated with the target rate basis or target price basis.
- Hedging substitutes basis risk for price risk.
- Hedging non-Treasury securities with Treasury bond futures requires that the hedge ratio consider two relationships: (1) the cash price of the non-Treasury security and the cheapest-to-deliver issue, and (2) the price of the cheapest-to-deliver issue and the futures price.
- In computing the hedge ratio for nondeliverable securities, the yield beta should be considered; regression analysis is used to estimate the yield beta and captures the relationship between yield levels and yield spreads.
- After a target is determined and a hedge is set, the hedge must be monitored during its life and evaluated after it is over. It is important to ascertain the sources of error in a hedge in order to gain insights that can be used to advantage in subsequent hedges.
- Three popular hedge strategies using options are the protective put-buying strategy, the covered call-writing strategy, and the collar strategy.
- A manager can use a protective put-buying strategy to hedge against rising interest rates. A protective put-buying strategy is a simple combination of a long put option with a long position in a cash bond.
- A covered call-writing strategy involves selling call options against the bond portfolio. A covered call-writing strategy entails much more downside risk than buying a put to protect the value of the portfolio, and many managers do not consider covered call writing a hedge.
- It is not possible to say that the protective put-buying strategy or the covered call-writing strategy is necessarily the better or more correct options hedge. The best strategy (and the best strike prices) depends on the manager's view of the market.
- A collar strategy is a combination of a protective put-buying strategy and a covered call-writing strategy. A manager who implements a collar

strategy eliminates part of the portfolio's downside risk by giving up part of its upside potential.

- The steps in options hedging include determining the option contract that is the best hedging vehicle, finding the appropriate strike price, and determining the number of options contracts. At the outset of options hedging, a minimum effective sale price can be calculated for a protective put-buying strategy and a maximum effective sale price can be computed for a covered call-writing strategy.
- The best options contract to use depends on the option price, liquidity, and correlation with the bond(s) to be hedged.
- For a cross-hedge, the manager will want to convert the strike price for the options that are actually bought or sold into an equivalent strike price for the actual bonds being hedged. When using Treasury bond futures options, the hedge ratio is based on the relative dollar duration of the current portfolio, the cheapest-to-deliver issue, and the futures contract at the option expiration date, as well as the conversion factor for the cheapest-to-deliver issue.
- While there are some mechanical differences in the way options on physicals and options on futures are traded and there may be substantial differences in their liquidity, the basic economics of the hedging strategies are virtually identical for both contracts. Using options on physicals frequently relieves the manager of much of the basis risk associated with an options hedge.

CHAPTER
SIXTY-TWO

INTEREST-RATE SWAPS AND SWAPTIONS

Swaps and swaptions are also used extensively by market participants to control interest-rate risk. The most prevalent swap contract is an *interest-rate swap*. An interest-rate swap contract provides a vehicle for market participants to transform the nature of cash-flows and the interest-rate exposure of a portfolio or balance sheet. In this chapter we explain how to analyze interest-rate swaps. We will describe a generic interest-rate swap, the parties to a swap, the risk and return of a swap, and the economic interpretation of a swap. Then we look at how to compute the floating-rate payments and calculate the present value of these payments. Next, we will see how to calculate the fixed-rate payments given the swap rate. Before we look at how to calculate the value of a swap, we will see how to calculate the swap rate. Given the swap rate, we will then see how the value of a swap is determined after the inception of a swap. We also will discuss other types of swaps as well as options on swaps called *swaptions*. Swaptions are used ever more frequently as a tool for investors to control their interest-rate risk. These instruments are described in the latter part of the chapter and their valuation is described in Chapter 63.

DESCRIPTION OF AN INTEREST-RATE SWAP

In an *interest-rate swap,* two parties (called *counterparties*) agree to exchange periodic interest payments. The dollar amount of the interest payments exchanged is based on some predetermined dollar principal, which is called the *notional amount*.

The dollar amount each counterparty pays to the other is the agreed-on periodic interest rate times the notional amount. The only dollars that are exchanged between the parties are the interest payments, not the notional amount. Accordingly, the notional principal serves only as a scale factor to translate an interest rate into a cash flow. In the most common type of swap, one party agrees to pay the other party fixed interest payments at designated dates for the life of the contract. This party is referred to as the *fixed-rate payer*. The other party, who agrees to make interest-rate payments that float with some reference rate, is referred to as the *floating-rate payer*.

The reference rates that have been used for the floating-rate in an interest-rate swap are various money market rates: Treasury bill rate, the London Interbank Offered Rate (LIBOR), commercial paper rate, bankers acceptances rate, certificates of deposit rate, the federal funds rate, and the prime rate. The most common is the LIBOR. LIBOR is the rate at which prime banks offer to pay on Eurodollar deposits available to other prime banks for a given maturity. There is not just one rate but a rate for different maturities. For example, there is a one-month LIBOR, three-month LIBOR, and six-month LIBOR.

To illustrate an interest-rate swap, suppose that for the next five years party *X* agrees to pay party *Y* 10% per year, while party *Y* agrees to pay party *X* six-month LIBOR (the reference rate). Party *X* is a fixed-rate payer/floating-rate receiver, while party *Y* is a floating-rate payer/fixed-rate receiver. Assume that the notional amount is $50 million and that payments are exchanged every six months for the next five years. This means that every six months, party *X* (the fixed-rate payer/floating-rate receiver) will pay party *Y* $2.5 million (10% times $50 million divided by 2). The amount that party *Y* (the floating-rate payer/fixed-rate receiver) will pay party *X* will be six-month LIBOR times $50 million divided by 2. If six-month LIBOR is 7%, party *Y* will pay party *X* $1.75 million (7% times $50 million divided by 2). Note that we divide by 2 because one-half year's interest is being paid.

Interest-rate swaps are over-the-counter (OTC) instruments. This means that swaps are not traded on an exchange. An institutional investor wishing to enter into a swap transaction can do so through either a securities firm or a commercial bank that transacts in swaps. These entities can do one of the following. First, they can arrange or broker a swap between two parties that want to enter into an interest-rate swap. In this case, the securities firm or commercial bank is acting in a brokerage capacity.

The second way in which a securities firm or commercial bank can get an institutional investor into a swap position is by taking the other side of the swap. This means that the securities firm or the commercial bank is a dealer rather than a broker in the transaction. Acting as a dealer, the securities firm or the commercial bank must hedge its swap position in the same way that it hedges its position in other securities. Also, it means that the swap dealer is the counterparty to the transaction.

The risks that the two parties take on when they enter into a swap is that the other party will fail to fulfill its obligations as set forth in the swap agreement. That is, each party faces default risk. The default risk in a swap agreement is

called *counterparty risk*. In any agreement between two parties that must perform according to the terms of a contract, counterparty risk is the risk that the other party will default. With futures and exchange-traded options, the counterparty risk is the risk that the clearinghouse will default. Market participants view this risk as small. In contrast, counterparty risk in a swap can be significant.

Because of counterparty risk, not all securities firms and commercial banks can be swap dealers. Several securities firms have established subsidiaries that are separately capitalized so that they have a high credit rating that permits them to enter into swap transactions as a dealer.

Thus it is imperative to keep in mind that any party who enters into a swap is subject to counterparty risk.

INTERPRETING A SWAP POSITION

There are two ways that a swap position can be interpreted: (1) a package of forward/futures contracts and (2) a package of cash-flows from buying and selling cash market instruments.

Package of Forward Contracts

Consider the hypothetical interest-rate swap used earlier to illustrate a swap. Let's look at party *X*'s position. Party *X* has agreed to pay 10% and receive six-month LIBOR. More specifically, assuming a $50 million notional amount, *X* has agreed to buy a commodity called "six-month LIBOR" for $2.5 million. This is effectively a six-month forward contract where *X* agrees to pay $2.5 million in exchange for delivery of six-month LIBOR. The fixed-rate payer is effectively long a six-month forward contract on six-month LIBOR. The floating-rate payer is effectively short a six-month forward contract on six-month LIBOR. There is therefore an implicit forward contract corresponding to each exchange date.

Consequently, interest-rate swaps can be viewed as a package of more basic interest-rate derivative instruments—forwards. The pricing of an interest-rate swap then will depend on the price of a package of forward contracts with the same settlement dates in which the underlying for the forward contract is the same reference rate.

While an interest-rate swap may be nothing more than a package of forward contracts, it is not a redundant contract for several reasons. First, maturities for forward or futures contracts do not extend out as far as those of an interest-rate swap; an interest-rate swap with a term of 15 years or longer can be obtained. Second, an interest-rate swap is a more transactionally efficient instrument. By this we mean that in one transaction an entity can effectively establish a payoff equivalent to a package of forward contracts. The forward contracts would each have to be negotiated separately. Third, the interest-rate swap market has grown in liquidity since its establishment in 1981; interest-rate swaps now provide more liquidity than forward contracts, particularly long-dated (i.e., long-term) forward contracts.

Package of Cash-Market Instruments

To understand why a swap also can be interpreted as a package of cash-market instruments, consider an investor who enters into the transaction below:

- Buy $50 million par value of a five-year floating-rate bond that pays six-month LIBOR every six months
- Finance the purchase by borrowing $50 million for five years at a 10% annual interest rate paid every six months.

The cash-flows for this transaction are set forth in Exhibit 62–1. The second column of the exhibit shows the cash-flows from purchasing the five-year floating-rate bond. There is a $50 million cash outlay and then 10 cash inflows. The amount of the cash inflows is uncertain because they depend on future levels of six-month LIBOR. The next column shows the cash-flows from borrowing $50 million on a fixed-rate basis. The last column shows the net cash-flows from the entire transaction. As the last column indicates, there is no initial cash-flow (the cash inflow and cash

EXHIBIT 62–1

Cash-Flows for the Purchase of a Five-Year Floating-Rate Bond Financed by Borrowing on a Fixed-Rate Basis

Transaction:

- Purchase for $50 million a five-year floating-rate bond:
  Floating-rate = LIBOR, semiannual pay
- Borrow $50 million for five years:
  Fixed-rate = 10%, semiannual payments

Six-Month Period	*Cash-Flow (in Millions of Dollars) from*		
	Floating-Rate Bond*	**Borrowing Cost**	**Net**
0	–$50	+$50.0	$0
1	$+ (\text{LIBOR}_1/2) \times 50$	–2.5	$+ (\text{LIBOR}_1/2) \times 50 - 2.5$
2	$+ (\text{LIBOR}_2/2) \times 50$	–2.5	$+ (\text{LIBOR}_2/2) \times 50 - 2.5$
3	$+ (\text{LIBOR}_3/2) \times 50$	–2.5	$+ (\text{LIBOR}_3/2) \times 50 - 2.5$
4	$+ (\text{LIBOR}_4/2) \times 50$	–2.5	$+ (\text{LIBOR}_4/2) \times 50 - 2.5$
5	$+ (\text{LIBOR}_5/2) \times 50$	–2.5	$+ (\text{LIBOR}_5/2) \times 50 - 2.5$
6	$+ (\text{LIBOR}_6/2) \times 50$	–2.5	$+ (\text{LIBOR}_6/2) \times 50 - 2.5$
7	$+ (\text{LIBOR}_7/2) \times 50$	–2.5	$+ (\text{LIBOR}_7/2) \times 50 - 2.5$
8	$+ (\text{LIBOR}_8/2) \times 50$	–2.5	$+ (\text{LIBOR}_8/2) \times 50 - 2.5$
9	$+ (\text{LIBOR}_9/2) \times 50$	–2.5	$+ (\text{LIBOR}_9/2) \times 50 - 2.5$
10	$+ (\text{LIBOR}_{10}/2) \times 50 + 50$	–52.5	$+ (\text{LIBOR}_{10}/2) \times 50 - 2.5$

*The subscript for LIBOR indicates the six-month LIBOR as per the terms of the floating-rate bond at time *t*.

outlay offset each other). In all 10 six-month periods, the net position results in a cash inflow of LIBOR and a cash outlay of $2.5 million. This net position, however, is identical to the position of a fixed-rate payer/floating-rate receiver.

It can be seen from the net cash-flow in Exhibit 62–1 that a fixed-rate payer has a cash market position that is equivalent to a long position in a floating-rate bond and a short position in a fixed-rate bond—the short position being the equivalent of borrowing by issuing a fixed-rate bond.

What about the position of a floating-rate payer? It can be easily demonstrated that the position of a floating-rate payer is equivalent to purchasing a fixed-rate bond and financing that purchase at a floating-rate, where the floating-rate is the reference rate for the swap. That is, the position of a floating-rate payer is equivalent to a long position in a fixed-rate bond and a short position in a floating-rate bond.

TERMINOLOGY, CONVENTIONS, AND MARKET QUOTES

Here we review some of the terminology used in the swaps market and explain how swaps are quoted. The *trade date* for a swap is the date on which the swap is transacted. The terms of the trade include the fixed interest rate, the maturity, the notional amount of the swap, and the payment bases of both legs of the swap. The date from which floating interest payments are determined is the *reset* or *setting date,* which also may be the trade date. In the same way as for FRAs (discussed in Chapter 59), the rate is fixed two business days before the interest period begins. The second (and subsequent) reset date will be two business days before the beginning of the second (and subsequent) swap periods. The *effective date* is the date from which interest on the swap is calculated, and this is typically two business days after the trade date. In a *forward-start swap,* the effective date will be at some point in the future, specified in the swap terms. The floating interest rate for each period is fixed at the start of the period, so the interest payment amount is known in advance by both parties (the fixed-rate is known, of course, throughout the swap by both parties).

While our illustrations assume that the timing of the cash-flows for both the fixed-rate payer and floating-rate payer will be the same, this is rarely the case in a swap. An agreement may call for the fixed-rate payer to make payments annually but the floating-rate payer to make payments more frequently (semiannually or quarterly). Also, the way in which interest accrues on each leg of the transaction differs. Normally, the fixed interest payments are paid on the basis of a 30/360 day count. Floating-rate payments for dollar and euro-denominated swaps use an actual/360-day count similar to other money market instruments in those currencies. Sterling-denominated swaps use an actual/365-day count.

Accordingly, the fixed interest payments will differ slightly owing to the differences in the lengths of successive coupon periods. The floating payments will differ owing to day counts as well as movements in the reference rate.

The terminology used to describe the position of a party in the swap markets combines cash-market jargon and futures-market jargon, given that a swap position can be interpreted either as a position in a package of cash-market instruments or a package of futures/forward positions. As we have said, the counterparty to an interest-rate swap is either a fixed-rate payer or floating-rate payer.

The fixed-rate payer receives floating-rate interest and is said to be "long" or to have "bought" the swap. The long side has conceptually purchased a floating-rate note (because it receives floating-rate interest) and issued a fixed-coupon bond (because it pays out fixed interest at periodic intervals). In essence, the fixed-rate payer is borrowing at fixed-rate and investing in a floating-rate asset. The floating-rate payer is said to be "short" or to have "sold" the swap. The short side has conceptually purchased a coupon bond (because it receives fixed-rate interest) and issued a floating-rate note (because it pays floating-rate interest). A floating-rate payer is borrowing at floating-rate and investing in a fixed-rate asset.

The convention that has evolved for quoting swaps levels is that a swap dealer sets the floating-rate equal to the reference rate and then quotes the fixed-rate that will apply. To illustrate this convention, consider the following 10-year swap terms available from a dealer:

- *Floating-rate payer:* Pay floating-rate of three-month LIBOR quarterly. Receive fixed-rate of 8.75% semiannually.
- *Fixed-rate payer:* Pay fixed-rate of 8.85% semiannually. Receive floating-rate of three-month LIBOR quarterly.

The offer price that the dealer would quote the fixed-rate payer would be to pay 8.85% and receive LIBOR "flat." (The word *flat* means with no spread.) The bid price that the dealer would quote the floating-rate payer would be to pay LIBOR flat and receive 8.75%. The bid-offer spread is 10 basis points.

In order to solidify our intuition, it is useful to think of the swap market as a market where two counterparties trade the floating reference rate in a series of exchanges for a fixed price. In effect, the swap market is a market to buy and sell LIBOR. Thus, buying a swap (pay fixed/receive floating) can be thought of as buying LIBOR on each reset date for the fixed-rate agreed to on the trade date. Conversely, selling a swap (receive fixed/pay floating) is effectively selling LIBOR on each reset date for a fixed-rate agreed to on the trade date. In this framework, a dealer's bid-offer spread can be easily interpreted. Using the numbers presented earlier, the bid price of 8.75% is the price the dealer will pay to the counterparty to receive three-month LIBOR. In other words, buy LIBOR at the bid. Similarly, the offer price of 8.85% is the price the dealer receives from the counterparty in exchange for three-month LIBOR. In other words, sell LIBOR at the offer.

The fixed-rate is some spread above the Treasury yield-curve with the same term-to-maturity as the swap. In our illustration, suppose that the 10-year Treasury yield is 8.35%. Then the offer price that the dealer would quote to the fixed-rate payer is the 10-year Treasury rate plus 50 basis points versus receiving LIBOR flat. For the floating-rate payer, the bid price quoted would be LIBOR flat versus

the 10-year Treasury rate plus 40 basis points. The dealer would quote such a swap as 40-50, meaning that the dealer is willing to enter into a swap to receive LIBOR and pay a fixed-rate equal to the 10-year Treasury rate plus 40 basis points, and he would be willing to enter into a swap to pay LIBOR and receive a fixed-rate equal to the 10-year Treasury rate plus 50 basis points.

VALUING INTEREST-RATE SWAPS

In an interest-rate swap, the counterparties agree to exchange periodic interest payments. The dollar amount of the interest payments exchanged is based on the notional principal. In the most common type of swap, there is a fixed-rate payer and a fixed-rate receiver. The convention for quoting swap rates is that a swap dealer sets the floating-rate equal to the reference rate and then quotes the fixed-rate that will apply.

Computing the Payments for a Swap

In the preceding section we described in general terms the payments by the fixed-rate payer and fixed-rate receiver, but we did not give any details. That is, we explained that if the swap rate is 6% and the notional amount is $100 million, then the fixed-rate payment will be $6 million for the year, and the payment is then adjusted based on the frequency of settlement. Thus, if settlement is semiannual, the payment is $3 million. If it is quarterly, it is $1.5 million. Similarly, the floating-rate payment would be found by multiplying the reference rate by the notional amount and then scaling based on the frequency of settlement.

It was useful to illustrate the basic features of an interest-rate swap with simple calculations for the payments such as described earlier and then explain how the parties to a swap either benefit or hurt when interest rates change. However, we will show how to value a swap in this section. To value a swap, it is necessary to determine both the present value of the fixed-rate payments and the present value of the floating-rate payments. The difference between these two present values is the value of a swap. As will be explained below, whether the value is positive (i.e., an asset) or negative (i.e., a liability) will depend on the party.

At the inception of the swap, the terms of the swap will be such that the present value of the floating-rate payments is equal to the present value of the fixed-rate payments. That is, the value of the swap is equal to zero at its inception. This is the fundamental principle in determining the swap rate (i.e., the fixed-rate that the fixed-rate payer will make).

Here is a roadmap of the presentation. First, we will look at how to compute the floating-rate payments. We will see how the future values of the reference rate are determined to obtain the floating-rate for the period. From the future values of the reference rate we will then see how to compute the floating-rate payments, taking into account the number of days in the payment period. Next,

we will see how to calculate the fixed-rate payments given the swap rate. Before we look at how to calculate the value of a swap, we will see how to calculate the swap rate. This will require an explanation of how the present value of any cash-flow in an interest-rate swap is computed. Given the floating-rate payments and the present value of the floating-rate payments, the swap rate can be determined by using the principle that the swap rate is the fixed-rate that will make the present value of the fixed-rate payments equal to the present value of the floating-rate payments. Finally, we will see how the value of swap is determined after the inception of a swap.

Calculating the Floating-Rate Payments

For the first floating-rate payment, the amount is known. For all subsequent payments, the floating-rate payment depends on the value of the reference rate when the floating-rate is determined. To illustrate the issues associated with calculating the floating-rate payment, we will assume that

- A swap starts today, January 1 of year 1 (swap settlement date).
- The floating-rate payments are made quarterly based on "actual/360."
- The reference rate is three-month LIBOR.
- The notional amount of the swap is $100 million.
- The term of the swap is three years.

The quarterly floating-rate payments are based on an actual/360-day count convention. Recall that this convention means that 360 days are assumed in a year and that in computing the interest for the quarter, the actual number of days in the quarter is used. The floating-rate payment is set at the beginning of the quarter but paid at the end of the quarter—that is, the floating-rate payments are made in arrears.

Suppose that today three-month LIBOR is 4.05%. Let's look at what the fixed-rate payer will receive on March 31 of year 1—the date when the first quarterly swap payment is made. There is no uncertainty about what the floating-rate payment will be. In general, the floating-rate payment is determined as follows:

$$\text{Notional amount} \times (\text{three-month LIBOR}) \times \frac{\text{no. of days in period}}{360}$$

In our illustration, assuming a nonleap year, the number of days from January 1 of year 1 to March 31 of year 1 (the first quarter) is 90. If three-month LIBOR is 4.05%, then the fixed-rate payer will receive a floating-rate payment on March 31 of year 1 equal to

$$\$100,000,000 \times 0.0405 \times \frac{90}{360} = \$1,012,500$$

Now the difficulty is in determining the floating-rate payment after the first quarterly payment. That is, for the three-year swap, there will be 12 quarterly floating-rate payments. Thus, while the first quarterly payment is known, the next 11 are not. However, there is a way to hedge the next 11 floating-rate payments by using a futures contract. Specifically, the futures contract used to hedge the future floating-rate payments in a swap whose reference rate is three-month LIBOR is the Eurodollar futures contract.

Determining Future Floating-Rate Payments

Now let's determine the future floating-rate payments. These payments can be locked in over the life of the swap using the Eurodollar futures contract. We will show how these floating-rate payments are computed using this contract.

We will begin with the next quarterly payment—from April 1 of year 1 to June 30 of year 1. This quarter has 91 days. The floating-rate payment will be determined by three-month LIBOR on April 1 of year 1 and paid on June 30 of year 1. Where might the fixed-rate payer look today (January 1 of year 1) to project what three-month LIBOR will be on April 1 of year 1? One possibility is the Eurodollar futures market. There is a three-month Eurodollar futures contract for settlement on June 30 of year 1. That futures contract will express the market's expectation of three-month LIBOR on April 1 of year 1. For example, if the futures price for the three-month Eurodollar futures contract that settles on June 30 of year 1 is 95.85, then as explained earlier, the three-month Eurodollar futures rate is 4.15%. We will refer to that rate for three-month LIBOR as the "forward rate." Therefore, if the fixed-rate payer bought 100 of these three-month Eurodollar futures contracts on January 1 of year 1 (the inception of the swap) that settle on June 30 of year 1, then the payment that will be locked in for the quarter (April 1 to June 30 of year 1) is

$$\$100,000,000 \times 0.0415 \times \frac{91}{360} = \$1,049,028$$

Note that each futures contract is for $1 million, and hence 100 contracts have a notional amount of $100 million.

Similarly, the Eurodollar futures contract can be used to lock in a floating-rate payment for each of the next 10 quarters. Once again, it is important to emphasize that the reference rate at the beginning of period t determines the floating-rate that will be paid for the period. However, the floating-rate payment is not made until the end of period t.

Exhibit 62–2 shows this for the three-year swap. Shown in column (1) is when the quarter begins and in column (2) when the quarter ends. The payment will be received at the end of the first quarter (March 31 of year 1) and is $1,012,500. This is the known floating-rate payment, as explained earlier. It is the only payment that is known. The information used to compute the first payment

EXHIBIT 62–2

Floating-Rate Payments Based on Initial LIBOR and Eurodollar Futures

Quarter Starts	Quarter Ends	Number of Days in Quarter	Current Three-Month LIBOR	Eurodollar Futures Price	Forward Rate	Period = End of Quarter	Floating-Rate Payment at End of Quarter
Jan 1 year 1	Mar 31 year 1	90	4.05%		—	1	1,012,500
Apr 1 year 1	June 30 year 1	91		95.85	4.15%	2	1,049,028
July 1 year 1	Sept 30 year 1	92		95.45	4.55%	3	1,162,778
Oct 1 year 1	Dec 31 year 1	92		95.28	4.72%	4	1,206,222
Jan 1 year 2	Mar 31 year 2	90		95.10	4.90%	5	1,225,000
Apr 1 year 2	June 30 year 2	91		94.97	5.03%	6	1,271,472
July 1 year 2	Sept 30 year 2	92		94.85	5.15%	7	1,316,111
Oct 1 year 2	Dec 31 year 2	92		94.75	5.25%	8	1,341,667
Jan 1 year 3	Mar 31 year 3	90		94.60	5.40%	9	1,350,000
Apr 1 year 3	June 30 year 3	91		94.50	5.50%	10	1,390,278
July 1 year 3	Sept 30 year 3	92		94.35	5.65%	11	1,443,889
Oct 1 year 3	Dec 31 year 3	92		94.24	5.76%	12	1,472,000

is in column (4), which shows the current three-month LIBOR (4.05%). The payment is shown in the last column, column (8).

Notice that column (7) numbers the quarters from 1 through 12. Look at the heading for column (7). It identifies each quarter in terms of the end of the quarter. This is important because we will eventually be discounting the payments (cash-flows). We must take care to understand when each payment is to be exchanged in order to properly discount. Thus, for the first payment of $1,012,500, it is going to be received at the end of quarter 1. When we refer to the time period for any payment, the reference is to the end of quarter. Thus the fifth payment of $1,225,000 would be identified as the payment for period 5, where period 5 means that it will be exchanged at the end of the fifth quarter.

Calculating the Fixed-Rate Payments

The swap will specify the frequency of settlement for the fixed-rate payments. The frequency need not be the same as the floating-rate payments. For example, in the three-year swap we have been using to illustrate the calculation of the floating-rate payments, the frequency is quarterly. The frequency of the fixed-rate payments could be semiannual rather than quarterly.

In our illustration we will assume that the frequency of settlement is quarterly for the fixed-rate payments, the same as with the floating-rate payments. The day-count convention is the same as for the floating-rate payment, actual/360. The equation for determining the dollar amount of the fixed-rate payment for the period is

$$\text{Notional amount} \times (\text{swap rate}) \times \frac{\text{no. of days in period}}{360}$$

It is the same equation as for determining the floating-rate payment except that the swap rate is used instead of the reference rate (three-month LIBOR in our illustration).

For example, suppose that the swap rate is 4.98% and the quarter has 90 days. Then the fixed-rate payment for the quarter is

$$\$100,000,000 \times 0.0498 \times \frac{90}{360} = \$1,245,000$$

If there are 92 days in a quarter, the fixed-rate payment for the quarter is

$$\$100,000,000 \times 0.0498 \times \frac{92}{360} = \$1,272,667$$

Note that the rate is fixed for each quarter, but the dollar amount of the payment depends on the number of days in the period.

Exhibit 62–3 shows the fixed-rate payments based on different assumed values for the swap rate. The first three columns of the exhibit show the same information as in Exhibit 62–2—the beginning and end of the quarter and the number of days in the quarter. Column (4) simply uses the notation for the period.

EXHIBIT 62–3

Fixed-Rate Payments for Several Assumed Swap Rates

(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)

Oct 1 year 2	Dec 31 year 2	92	8	1,272,667	1,274,532	1,274,558	1,274,583	1,274,711
Jan 1 year 3	Mar 31 year 3	90	9	1,245,000	1,246,825	1,246,850	1,246,875	1,247,000
Apr 1 year 3	June 30 year 3	91	10	1,258,833	1,260,679	1,260,704	1,260,729	1,260,856
July 1 year 3	Sept 30 year 3	92	11	1,272,667	1,274,532	1,274,558	1,274,583	1,274,711
Oct 1 year 3	Dec 31 year 3	92	12	1,272,667	1,274,532	1,274,558	1,274,583	1,274,711

That is, period 1 means the end of the first quarter, period 2 means the end of the second quarter, and so on. The other columns of the exhibit show the payments for each assumed swap rate.

Calculation of the Swap Rate

Now that we know how to calculate the payments for the fixed-rate and floating-rate sides of a swap where the reference rate is three-month LIBOR given (1) the current value for three-month LIBOR, (2) the expected three-month LIBOR from the Eurodollar futures contract, and (3) the assumed swap rate, we can demonstrate how to compute the swap rate.

At the initiation of an interest-rate swap, the counterparties are agreeing to exchange future payments, and no upfront payments are made by either party. This means that the swap terms must be such that the present value of the payments to be made by the counterparties must be at least equal to the present value of the payments that will be received. In fact, to eliminate arbitrage opportunities, the present value of the payments made by a party will be equal to the present value of the payments received by that same party. *The equivalence (or no arbitrage) of the present value of the payments is the key principle in calculating the swap rate.*

Since we will have to calculate the present value of the payments, let's show how this is done.

Calculating the Present Value of the Floating-Rate Payments

As explained earlier, we must be careful about how we compute the present value of payments. In particular, we must carefully specify (1) the timing of the payment and (2) the interest rates that should be used to discount the payments. We have already addressed the first issue. In constructing the exhibit for the payments, we indicated that the payments are at the end of the quarter. Thus we denoted the time periods with respect to the end of the quarter.

Now let's turn to the interest rates that should be used for discounting. First, every cash-flow should be discounted at its own discount rate using a spot rate. Thus, if we discounted a cash-flow of \$1 using the spot rate for period t, the present value would be

$$\text{Present value of \$1 to be received in period } t = \frac{\$1}{(1 + \text{spot rate for period } t)^t}$$

Second, forward rates are derived from spot rates, so if we discounted a cash-flow using forward rates rather than spot rates, we would come up with the same value. That is, the present value of \$1 to be received in period t can be rewritten as

$$\text{Present value of \$1 to be received in period } t \text{ discounted with forward rates}$$
$$= \frac{\$1}{(1 + \text{forward rate for period } 1)(1 + \text{forward rate for period } 2)\cdots(1 + \text{forward rate for period } t)}$$

We will call the present value of \$1 to be received in period t as the *forward discount factor*. In our calculations involving swaps, we will compute the forward discount factor for a period using the forward rates. These are the same forward rates that are used to compute the floating-rate payments—those obtained from the Eurodollar futures contract. We must make just one more adjustment. We must adjust the forward rates used in the formula for the number of days in the period (i.e., the quarter in our illustrations) in the same way that we made this adjustment to obtain the payments. Specifically, the forward rate for a period, which we will call the *period forward rate,* is computed using the following equation:

$$\text{Period forward rate} = \text{annual forward rate} \times \left(\frac{\text{days in period}}{360}\right)$$

For example, look at Exhibit 62–2. The annual forward rate for period 4 is 4.72%. The period forward rate for period 4 is

$$\text{Period forward rate} = 4.72\% \times \left(\frac{92}{360}\right) = 1.2062\%$$

Column (5) in Exhibit 62–4 shows the annual forward rate for all 12 periods (reproduced from Exhibit 62–3), and column (6) shows the period forward rate for all 12 periods. Note that the period forward rate for period 1 is 4.05%, the known rate for three-month LIBOR.

Also shown in Exhibit 62–4 is the forward discount factor for all 12 periods. These values are shown in the last column. Let's show how the forward discount factor is computed for periods 1, 2, and 3. For period 1, the forward discount factor is

$$\text{Forward discount factor} = \frac{\$1}{(1.010125)} = 0.98997649$$

For period 2,

$$\text{Forward discount factor} = \frac{\$1}{(1.010125)(1.010490)} = 0.97969917$$

For period 3,

$$\text{Forward discount factor} = \frac{\$1}{(1.010125)(1.010490)(1.011628)} = 0.96843839$$

Given the floating-rate payment for a period and the forward discount factor for the period, the present value of the payment can be computed. For example, from Exhibit 62–2 we see that the floating-rate payment for period 4 is \$1,206,222. From Exhibit 62–4, the forward discount factor for period 4 is 0.95689609. Therefore, the present value of the payment is

$$\begin{aligned}\text{Present value of period 4 payment} &= \$1{,}206{,}222 \times 0.95689609 \\ &= \$1{,}154{,}229\end{aligned}$$

EXHIBIT 62–4

Calculating the Forward Discount Factor

(1)	(2)	(3)	(4)	(5)	(6)	(7)
Quarter Starts	**Quarter Ends**	**Number of Days in Quarter**	**Period = End of Quarter**	**Forward Rate**	**Period Forward Rate**	**Forward Discount Factor**
Jan 1 year 1	Mar 31 year 1	90	1	4.05%	1.0125%	0.98997649
Apr 1 year 1	June 30 year 1	91	2	4.15%	1.0490%	0.97969917
July 1 year 1	Sept 30 year 1	92	3	4.55%	1.1628%	0.96843839
Oct 1 year 1	Dec 31 year 1	92	4	4.72%	1.2062%	0.95689609
Jan 1 year 2	Mar 31 year 2	90	5	4.90%	1.2250%	0.94531597
Apr 1 year 2	June 30 year 2	91	6	5.03%	1.2715%	0.93344745
July 1 year 2	Sept 30 year 2	92	7	5.15%	1.3161%	0.92132183
Oct 1 year 2	Dec 31 year 2	92	8	5.25%	1.3417%	0.90912441
Jan 1 year 3	Mar 31 year 3	90	9	5.40%	1.3500%	0.89701471
Apr 1 year 3	June 30 year 3	91	10	5.50%	1.3903%	0.88471472
July 1 year 3	Sept 30 year 3	92	11	5.65%	1.4439%	0.87212224
Oct 1 year 3	Dec 31 year 3	92	12	5.76%	1.4720%	0.85947083

Exhibit 62–5 shows the present value for each payment. The total present value of the 12 floating-rate payments is $14,052,917 Thus the present value of the payments that the fixed-rate payer will receive is $14,052,917, and the present value of the payments that the fixed-rate receiver will make is $14,052,917.

Determination of the Swap Rate

The fixed-rate payer will require that the present value of the fixed-rate payments that must be made based on the swap rate not exceed the $14,052,917 payments to be received from the floating-rate payments. The fixed-rate receiver will require that the present value of the fixed-rate payments to be received is at least as great as the $14,052,917 that must be paid. This means that both parties will require a present value for the fixed-rate payments to be $14,052,917. If this is the case, the present value of the fixed-rate payments is equal to the present value of the floating-rate payments, and therefore, the value of the swap is zero for both parties at the inception of the swap. The interest rates that should be used to compute the present value of the fixed-rate payments are the same interest rates as those used to discount the floating-rate payments.

To show how to compute the swap rate, we begin with the basic relationship for no arbitrage to exist:

$$PV \text{ of floating-rate payments} = PV \text{ of fixed-rate payments}$$

We know the value for the left-hand side of the equation.

If we let

$$SR = \text{swap rate}$$

and

$$\text{Days}_t = \text{number of days in the payment period } t$$

then the fixed-rate payment for period t is equal to

$$\text{Notional amount} \times SR \times \frac{\text{days}_t}{360}$$

The present value of the fixed-rate payment for period t is found by multiplying the previous expression by the forward discount factor. If we let FDF_t denote the forward discount factor for period t, then the present value of the fixed-rate payment for period t is equal to

$$\text{Notional amount} \times SR \times \frac{\text{days}_t}{360} \times FDF_t$$

We can now sum up the present value of the fixed-rate payment for each period to get the present value of the floating-rate payments. Using the Greek

EXHIBIT 62–5

Jan 1 year 2	Mar 31 year 2	5	0.94531597	1,225,000	1,158,012
Apr 1 year 2	June 30 year 2	6	0.93344745	1,271,472	1,186,852
July 1 year 2	Sept 30 year 2	7	0.92132183	1,316,111	1,212,562
Oct 1 year 2	Dec 31 year 2	8	0.90912441	1,341,667	1,219,742
Jan 1 year 3	Mar 31 year 3	9	0.89701471	1,350,000	1,210,970
Apr 1 year 3	June 30 year 3	10	0.88471472	1,390,278	1,229,999
July 1 year 3	Sept 30 year 3	11	0.87212224	1,443,889	1,259,248
Oct 1 year 3	Dec 31 year 3	12	0.85947083	1,472,000	1,265,141
TOTAL					14,052,917

symbol sigma (Σ) to denote summation, and letting N be the number of periods in the swap, then the present value of the fixed-rate payments can be expressed as

$$\sum_{t=1}^{N} \text{notional amount} \times SR \times \frac{\text{days}_t}{360} \times FDF_t$$

This also can be expressed as

$$SR \sum_{t=1}^{N} \text{notional amount} \times \frac{\text{days}_t}{360} \times FDF_t$$

The condition for no arbitrage is that the present value of the fixed-rate payments as given by the preceding expression is equal to the present value of the floating-rate payments. That is,

$$SR \sum_{t=1}^{N} \text{notional amount} \times \frac{\text{days}_t}{360} \times FDF_t = PV \text{ of floating-rate payments}$$

Solving for the swap rate,

$$SR = \frac{PV \text{ of floating-rate payments}}{\sum_{t=1}^{N} \text{notional amount} \times \frac{\text{days}_t}{360} \times FDF_t}$$

All the values needed to compute the swap rate are known.

Let's apply the formula to determine the swap rate for our three-year swap. Exhibit 62–6 shows the calculation of the denominator of the formula. The forward discount factor for each period shown in column (5) is obtained from column (4) of Exhibit 62–5. The sum of the last column in Exhibit 62–6 shows that the denominator of the swap-rate formula is $281,764,282. We know from Exhibit 62–5 that the present value of the floating-rate payments is $14,052,917. Therefore, the swap rate is

$$SR = \frac{\$14,052,917}{\$281,764,282} = 0.049875 = 4.9875\%$$

Given the swap rate, the *swap spread* can be determined. For example, since this is a three-year swap, the convention is to use the three-year on-the-run Treasury rate as the benchmark. If the yield on that issue is 4.5875%, the swap spread is 40 basis points (4.9875% – 4.5875%).

The calculation of the swap rate for all swaps follows the same principle: equating the present value of the fixed-rate payments to that of the floating-rate payments.

Valuing a Swap

Once the swap transaction is completed, changes in market interest rates will change the payments of the floating-rate side of the swap. The value of an interest-rate swap

is the difference between the present value of the payments of the two sides of the swap. The three-month LIBOR forward rates from the current Eurodollar futures contracts are used to (1) calculate the floating-rate payments and (2) determine the discount factors at which to calculate the present value of the payments.

To illustrate this, consider the three-year swap used to demonstrate how to calculate the swap rate. Suppose that one year later, interest rates change as shown in columns (4) and (6) in Exhibit 62–7. Column (4) shows the current three-month LIBOR. In column (5) are the Eurodollar futures price for each period. These rates are used to compute the forward rates in column (6). Note that the interest rates have increased one year later because the rates in Exhibit 62–7 are greater than those in Exhibit 62–2. As in Exhibit 62–2, the current three-month LIBOR and the forward rates are used to compute the floating-rate payments. These payments are shown in column (8) of Exhibit 62–7.

In Exhibit 62–8, the forward discount factor is computed for each period. The calculation is the same as in Exhibit 62–4 to obtain the forward discount factor for each period. The forward discount factor for each period is shown in the last column of Exhibit 62–8.

In Exhibit 62–9, the forward discount factor (from Exhibit 62–8) and the floating-rate payments (from Exhibit 62–7) are shown. The fixed-rate payments need not be recomputed. They are the payments shown in column (8) of Exhibit 62–3. These are fixed-rate payments for the swap rate of 4.9875% and are reproduced in Exhibit 62–9. Now the two payment streams must be discounted using the new forward discount factors. As shown at the bottom of Exhibit 62–9, the two present values are as follows:

Present value of floating-rate payments	\$11,459,495
Present value of fixed-rate payments	\$9,473,390

The two present values are not equal, and therefore, for one party, the value of the swap increased, and for the other party, the value of the swap decreased. Let's look at which party gained and which party lost.

The fixed-rate payer will receive the floating-rate payments. And these payments have a present value of \$11,459,495. The present value of the payments that must be made by the fixed-rate payer is \$9,473,390. Thus the swap has a positive value for the fixed-rate payer equal to the difference in the two present values of \$1,986,105. This is the value of the swap to the fixed-rate payer. Notice, consistent with what we said earlier, that when interest rates increase (as they did in our illustration), the fixed-rate payer benefits because the value of the swap increases.

In contrast, the fixed-rate receiver must make payments with a present value of \$11,459,495 but will only receive fixed-rate payments with a present value equal to \$9,473,390. Thus the value of the swap for the fixed-rate receiver is –\$1,986,105. Again, as explained earlier, the fixed-rate receiver is adversely affected by a rise in interest rates because it results in a decline in the value of a swap.

PV of payments made	9,473,390	11,459,495
Value of swap	1,986,105	–1,986,105

The same valuation principle applies to more complicated swaps. For example, there are swaps whose notional amount changes in a predetermined way over the life of the swap. These include amortizing swaps, accreting swaps, and roller-coaster swaps. Once the payments are specified, the present value is calculated as described earlier simply by adjusting the payment amounts by the changing notional amounts—the methodology does *not* change.

PRIMARY DETERMINANTS OF SWAP SPREADS

The swap spread is determined by the same factors that drive the spread over Treasuries on instruments that replicate a swap's cash-flows, i.e., produce a similar return or funding profile. As discussed below, the swap spread's key determinant for swaps with tenors (i.e., maturities) of five years or less is the cost of hedging in the Eurodollar futures market. Although listed contracts exist with delivery dates out to 10 years, the liquidity of the Eurodollar futures market diminishes considerably after about five years. For longer tenor swaps, the swap spread is largely driven by credit-spreads in the corporate bond market. Specifically, longer-dated swaps are priced relative to rates paid by investment-grade credits in traditional fixed- and floating-rate markets.

Given that a swap is a package of futures/forward contracts, the shorter-term swap spreads respond directly to fluctuations in Eurodollar futures prices. As noted, there is a liquid market for Eurodollar futures contracts with maturities every three months for approximately five years. A market participant can create a synthetic fixed-rate security or a fixed-rate funding vehicle by taking a position in a bundle of Eurodollar futures contracts (i.e., a position in every three-month Eurodollar futures contract up to the desired maturity date).

For example, consider a financial institution that has fixed-rate assets and floating-rate liabilities. Both the assets and liabilities have a maturity of three years. The interest rate on the liabilities resets every three months based on three-month LIBOR. This financial institution can hedge this mismatched asset/liability position by buying a three-year bundle of Eurodollar futures contracts. By doing so, the financial institution is receiving LIBOR over the three-year period and paying a fixed dollar amount (i.e., the futures price). The financial institution is now hedged because the assets are fixed-rate, and the bundle of long Eurodollar futures synthetically creates a fixed-rate funding arrangement. From the fixed dollar amount over the three years, an effective fixed-rate that the financial institution pays can be computed. Alternatively, the financial institution can synthetically create a fixed-rate funding arrangement by entering into a three-year swap in which it pays fixed and receives three-month LIBOR. Other things equal, the financial institution will use the vehicle that delivers the lowest cost of hedging the mismatched position. That is, the financial institution will compare the synthetic fixed-rate (expressed as a percentage over U.S. Treasuries) to the three-year

swap spread. The difference between the synthetic spread and the swap spread should be within a few basis points under normal circumstances.

For swaps with tenors greater than five years, we cannot rely on the Eurodollar futures owing to diminishing liquidity of such contracts. Instead, longer-dated swaps are priced using rates available for investment-grade corporate borrowers in fixed-rate and floating-rate debt markets. Since a swap can be interpreted as a package of long and short positions in a fixed-rate bond and a floating-rate bond, it is the credit-spreads in those two market sectors that will be the primary determinant of the swap spread. Empirically, the swap curve lies above the U.S. Treasury yield-curve and below the on-the-run yield-curve for AA-rated banks.[1] Swap fixed-rates are lower than AA-rated bond yields due to their lower credit risk due to netting and offsetting of swap positions.

In addition, there are a number of other technical factors that influence the level of swap spreads.[2] While the impact of some these factors is ephemeral, their influence can be considerable in the short run. Included among these factors are (1) the level and shape of the Treasury yield-curve, (2) the relative supply of fixed- and floating-rate payers in the interest-rate swap market, (3) the technical factors that affect swap dealers, and (4) the level of asset-based swap activity.

The level, slope, and curvature of the U.S. Treasury yield-curve are important influences on swap spreads at various maturities. The reason is that embedded in the yield-curve are the market's expectations of the direction of future interest rates. While these expectations are sometimes challenging to extract, the decision to borrow at a fixed-rate or a floating-rate will be based, in part, on these expectations. The relative supply of fixed- and floating-rate payers in the interest-rate swap market also should be influenced by these expectations. For example, many corporate issuers—financial institutions and federal agencies in particular—swap their newly issued fixed-rate debt into floating using the swap market. Consequently, swap spreads will be affected by the corporate debt issuance calendar. In addition, swap spreads, like credit-spreads, also tend to increase with the swap's tenor or maturity.

Swap spreads are also affected by the hedging costs faced by swap dealers. Dealers hedge the interest-rate risk of long (short) swap positions by taking a long (short) position in a Treasury security with the same maturity as the swap's tenor and borrowing funds (lending funds) in the repo market. As a result, the spread between LIBOR and the appropriate repo rate will be a critical determinant of the hedging costs. When on-the-run Treasuries go "on special," it is correspondingly

1. For a discussion of this point, see Andrew R. Young, *A Morgan Stanley Guide to Fixed-Income Analysis* (New York: Morgan Stanley, 1997).
2. See Ellen L. Evans and Gioia Parente Bales, "What Drives Interest-Rate Swap Spreads," Chapter 13 in Carl R. Beidleman (ed.), *Interest-Rate Swaps* (Burr Ridge, IL: Irwin Professional Publishing, 1991).

more expensive to use these Treasuries as a hedge. This increase in hedging costs results in wider swap spreads.[3]

Another influence on the level of swap spreads is the volume of asset-based swap transactions. An asset-based swap transaction involves the creation of a synthetic security via the purchase of an existing security and the simultaneous execution of a swap. For example, after the Russian debt default and devaluation in August 1998, risk-averse investors sold corporate bonds and fled to the relative safety of U.S. Treasuries. Credit-spreads widened considerably and liquidity diminished. A contrary-minded floating-rate investor (like a financial institution) could have taken advantage of these circumstances by buying newly issued investment-grade corporate bonds with relatively attractive coupon rates and simultaneously taking a long position in an interest-rate swap (pay fixed/receive floating). Accordingly, the financial institution ends up with a synthetic floating-rate asset with a spread above LIBOR.

By similar reasoning, investors can use swaps to create a synthetic fixed-rate security. For example, during the mid-1980s, many banks issued perpetual floating-rate notes in the Eurobond market. A perpetual floating-rate note is a security that delivers floating-rate cash-flows forever. The coupon is reset and paid usually every three months with a coupon formula equal to the reference rate (e.g., three-month LIBOR) plus a spread. When the perpetual floating-rate note market collapsed in late 1986, the contagion spread into other sectors of the floaters market.[4] Many floaters cheapened considerably. As before, contrary-minded fixed-rate investors could exploit this situation through the purchase of a relatively cheap (from the investor's perspective) floater while simultaneously taking a short position in an interest-rate swap (pay floating/receive fixed) thereby creating a synthetic fixed-rate investment. The investor makes floating-rate payments (say, based on LIBOR) to the counterparty and receives fixed-rate payments equal to the Treasury yield plus the swap spread. Accordingly, the fixed-rate on this synthetic security is equal to the sum of the following: (1) the Treasury bond yield that matches the swap's tenor, (2) the swap spread, and (3) the floater's index spread.

NONGENERIC INTEREST-RATE SWAPS

The swap market is very flexible, and instruments can be tailor-made to fit the requirements of individual customers. A wide variety of swap contracts are traded in the market. Although the most common reference rate for the floating leg of a swap is six-month LIBOR for a semiannual-paying floating leg, other reference rates that have been used include three-month LIBOR, the prime rate

3. Traders often use the repo market to obtain specific securities to cover short positions. If a security is in short supply relative to demand, the repo rate on a specific security used as collateral in a repo transaction will be below the general (i.e., generic) collateral repo rate. When a particular security's repo rate falls markedly, that security is said to be "on special." Investors who own these securities are able to lend them out as collateral and borrow at bargain basement rates.
4. Suresh E. Krishman, "Asset-Based Interest-Rate Swaps," Chapter 8 in *Interest-Rate Swaps*.

(for dollar swaps), the one-month commercial paper rate, the Treasury bill rate, and the municipal bond rate.

The term of a swap need not be fixed; swaps may be *extendible* or *putable*. In an extendible swap, one of the parties has the right but not the obligation to extend the life of the swap beyond the fixed maturity date, whereas in a putable swap one party has the right to terminate the swap prior to the specified maturity date.

It is also possible to transact options on swaps, known as *swaptions*. A swaption is the right to enter into a swap agreement at some point in the future during the life of the option. Essentially a swaption is an option to exchange a fixed-rate bond cash-flow for a floating-rate bond cash-flow structure. Swaptions will be described in more detail later. Other swaps are described below.

Constant-Maturity Swap

In a constant-maturity swap, the parties exchange a LIBOR rate for a fixed swap rate. For example, the terms of the swap might state that six-month LIBOR is exchanged for the five-year swap rate on a semiannual basis for the next five years or for the five-year government bond rate. In the U.S. market, the second type of constant-maturity swap is known as a *constant-maturity Treasury swap*.

Accreting and Amortizing Swaps

In a plain-vanilla swap, the notional principal remains unchanged during the life of the swap. However it is possible to trade a swap where the notional principal varies during its life. An accreting (or step-up) swap is one in which the principal starts off at one level and then increases in amount over time. The opposite, an amortizing swap, is one in which the notional reduces in size over time. An accreting swap would be useful where, for instance, a funding liability that is being hedged increases over time. The amortizing swap might be employed by a borrower hedging a bond issue that featured sinking-fund payments, where a part of the notional amount outstanding is paid off at set points during the life of the bond. If the principal fluctuates in amount, for example, increasing in one year and then reducing in another, the swap is known as a *roller-coaster swap*. Another application of an amortizing swap is as a hedge for a loan that is itself an amortizing one. Frequently this is combined with a forward-start swap to tie in with the cash-flows payable on the loan. The pricing and valuation of an amortizing swap are no different in principle to a vanilla interest-rate swap; a single swap rate is calculated using the relevant discount factors, and at this rate the net present value of the swap cash-flows will equal zero at the start of the swap.

Basis Swap

In a conventional swap, one leg comprises fixed-rate payments and the other floating-rate payments. In a *basis swap,* both legs are floating-rate but linked to

different money market indexes. One leg is normally linked to LIBOR, while the other might be linked to the CD rate or the commercial paper rate. This type of swap would be used by a bank in the United States that had made loans that paid at the prime rate and funded its loans at LIBOR. A basis swap would eliminate the basis risk between the bank's income and interest expense. Other basis swaps are traded in which both legs are linked to LIBOR, but at different maturities; for instance, one leg might be at three-month LIBOR and the other at six-month LIBOR. In such a swap, the basis is different as is the payment frequency: One leg pays out semiannually, while the other would be paying on a quarterly basis.

Off-Market Swap

When a swap is transacted, its fixed-rate is quoted at the current market rate for that maturity. When the fixed-rate is different from the market rate, this type of swap is an *off-market swap,* and a compensating payment is made by one party to the other. An off-market rate may be used for particular hedging requirements, for example, or when a bond issuer wishes to use the swap to hedge the bond as well as to cover the bond's issue costs.

Forward-Start Swap

A *forward-start swap* is an obligation where two counterparties agree to enter into a swap contract at some future date under terms negotiated today.[5] Accordingly, the swap's effective (i.e., start) date is not the usual one or two days after the trade date but some time afterwards, say, six months after the trade date: for example, an interest-rate swap with a tenor of three years that has an effective date one year from today. Once the effective date is reached, a forward-start swap is identical to a normal interest-rate swap. Earlier in the chapter we noted that it is useful to think of the generic interest-rate swap market as one where two counterparties trade the floating reference rate in a series of exchanges for a fixed price. Extending this intuition, the forward-start interest-rate swap market is a forward market for trading the floating reference rate as opposed to the spot market.

A forward-start swap contract will specify the swap's fixed-rate at which the two counterparties agree to exchange cash-flows during the swap's life which begins on some future effective date. This rate is referred to as the *forward swap fixed-rate.*

Overnight Interest-Rate Swaps and Eonia/SONIA Swaps

Overnight-index swaps (OIS) are interest-rate swaps that are traded in the money markets because of their short-term maturity but are generically identically to interest-rate swaps and so also may be considered a capital market instrument.

5. Forward-start swaps are also referred to as *forward swaps, delayed swaps,* and *deferred swaps.*

We saw earlier in this chapter that an interest-rate swap contract, which is generally regarded as a capital market instrument, is an agreement between two counterparties to exchange a fixed-interest-rate payment in return for a floating-interest-rate payment, calculated on a notional swap amount, at regular intervals during the life of the swap. A swap may be viewed as being equivalent to a series of successive forward contracts, with each forward contract starting as the previous one matures. The basis of the floating interest rate is agreed as part of the contract terms at the inception of the trade. Conventional swaps index the floating interest rate to LIBOR; however an exciting recent development in the money markets has been the OIS. In the sterling market they are known as *sterling overnight interest rate average swaps,* or SONIA, while Eurocurrency OIS are known as *Eonia*. In this section we review OIS swaps, which are used extensively by commercial and investment banks.

SONIA is the average interest rate of interbank (unsecured) overnight sterling deposit trades undertaken before 15:30 hours each day between members of the London Wholesale Money Brokers' Association. Recorded interest rates are weighted by volume. A SONIA swap is a swap contract that exchanges a fixed interest rate (the swap rate) against the geometric average of the overnight interest rates that have been recorded during the life of the contract. Exchange of interest takes place on maturity of the swap. SONIA swaps are used to speculate on or to hedge against interest rates at the very short end of the sterling yield-curve; in other words, they can be used to hedge an exposure to overnight interest rates.[6] The swaps themselves are traded in maturities of one week to one year, although two-year SONIA swaps have also been traded.

Conventional swap rates are calculated off the government bond yield-curve and represent the credit premium over government yields of interbank default risk. Essentially, they represent an average of the forward rates derived from the government spot (zero-coupon) yield-curve. The fixed-rate quoted on a SONIA swap represents the average level of the overnight interest rates expected by market participants over the life of the swap. In practice, the rate is calculated as a function of the Bank of England's repo rate. This is the two-week rate at which the Bank conducts reverse repo trades with banking counterparties as part of its open market operations. In other words, this is the Bank's base rate. In theory, one would expect the SONIA rate to follow the repo rate fairly closely, since the credit risk on an overnight deposit is low. However, in practice, the spread between the SONIA rate and the Bank repo rate is very volatile, and for this reason, the swaps are used to hedge overnight exposures.

Overnight-index swaps dealt in U.S. dollars are linked to the federal funds rate. Since this rate is considerably below the overnight LIBOR rate, it means that

6. Traditionally, overnight rates fluctuate in a very wide range during the day, depending on the day's funds shortage, and although volatility has reduced since the introduction of gilt repo, it is still unpredictable on occasion.

the swap is not always used by banks to hedge overnight interest rate liability exposure, especially when the latter is linked to LIBOR.

CANCELING A SWAP

When financial institutions enter into a swap contract in order to hedge interest-rate liabilities, the swap will be kept in place until its expiration. However, circumstances may change, or a financial institution may alter its view on interest rates, and so circumstances may arise such that it may be necessary to terminate the swap. The most straightforward option is for the corporation to take out a second contract that negates the first. This allows the first swap to remain in place, but there may be residual cash-flows unless the two swaps cancel each other out precisely. The terms for the second swap, being nonstandard (and unlikely to be exactly whole years to maturity, unless traded on the anniversary of the first), also may result in it being more expensive than a vanilla swap. Since it is unlikely that the second swap will have the same rate, the two fixed legs will not net to zero. And if the second swap is not traded on an anniversary, payment dates will not match.

For these reasons, an entity may wish to cancel the swap entirely. To do this, it will ask a swap market maker for a quotation on a *cancellation fee*. The bank will determine the cancellation fee by calculating the net present value of the remaining cash-flows in the swap using the relevant discount factor for each future cash-flow. In practice just the fixed leg will be present valued and then netted with LIBOR. The net present value of all the cash-flows is the fair price for canceling the swap. The valuation principles we established earlier will apply; that is, if the fixed-rate payer is asking to cancel the swap when interest rates have fallen, he will pay the cancellation fee, and vice versa if rates have risen.

CREDIT RISK

The rate quoted for swaps in the interbank market assumes that the counterparty to the transaction has a lending line with the swap bank, so the swap rate therefore reflects the credit risk associated with an interbank quality counterparty. This credit risk is reflected in the spread between the swap rate and the equivalent-maturity government bond, although, as noted, the spread also reflects other considerations such as liquidity and supply and demand. The credit risk of a swap is separate from its interest-rate risk or market risk, and arises from the possibility of the counterparty to the swap defaulting on its obligations. If the present value of the swap at the time of default is net positive, then a bank is at risk of loss of this amount. While market risk can be hedged, it is more problematic to hedge credit risk. The common measures taken include limits on lending lines, collateral, and diversification across counterparty sectors, as well as a form of credit value-at-risk to monitor credit exposures.

A bank therefore is at risk of loss due to counterparty default for all its swap transactions. If at the time of default, the net present value of the swap is positive, this amount is potentially at risk and will probably be written off. If the value of the swap is negative at the time of default, in theory this amount is a potential gain to the bank, although in practice the counterparty's administrators will try to recover the value for their client. In this case, then, there is no net gain or loss to the swap bank. The credit risk management department of a bank will therefore often assess the ongoing credit quality of counterparties with whom the swap transactions are currently positive in value.

SWAPTIONS

We conclude this chapter with a discussion of swaptions. A *swaption* is an option to establish a position in an interest-rate swap at some future date. The swaption contract specifies the swaption's expiration date, as well as the fixed-rate and tenor of the underlying swap. The swap's fixed-rate is called the swaption's *strike rate*. There are two types of swaptions—pay fixed or receive fixed. A pay (receive) fixed swaption gives the buyer the right to establish a position in an interest-rate swap where she will pay (receive) the fixed-rate cash-flows and receive (pay) the floating-rate cash-flows.

Let's illustrate a hypothetical swaption with a one-year swaption on a five-year generic interest-rate swap with a $10 million notional principal in which the buyer will receive fixed cash inflows and pay floating-rate cash-flows. Assume the swaption is European and is therefore exercisable only at expiration. Further assume the swap's fixed-rate is 3.35188% while the floating-rate is three-month LIBOR flat. If the swaption is exercised on its expiration date say, January 1, 2012, the five-year swap begins on January 1, 2012 at a fixed-rate of 3.35188% in exchange for floating cash flows and ends on January 1, 2017 ("maturity").

When valuing interest-rate derivatives or bonds with embedded options, it is essential to model expected future interest-rate volatility. Accordingly, the lattice approach discussed in Chapter 40 is a commonly used method to value swaptions. A swaption's value will depend on a few critical parameters that include market inputs (e.g., the current yield-curve) as well as terms of the swaption contract (e.g., time to expiration). To solidify our intuition about how swaptions work, we examine how changes in key factors affect swaption values. In particular, we will consider changes in the following: yield-curve (level and slope), volatility, strike rate, and time to expiration.

Changes in the Yield-Curve

As with conventional call and put options, pay-fixed or receive-fixed swaptions tend to react in an opposite manner to changes in the underlying parameters.

For example, a pay-fixed swaption increases in value with an upward parallel shift in the yield-curve, and a receive-fixed swaption becomes more valuable with a downward parallel shift in the yield-curve. To see this, consider a one-year European pay-fixed swaption on a five-year generic interest-rate swap. The notional principal is $10 million, and the strike rate is 6%. On the expiration date, the buyer will either exercise it (i.e., enter into the five-year swap to pay 6% fixed-rate cash-flows and receive floating-rate cash-flows) or let the swaption expire. If the five-year swap rate is above 6% on the expiration date, the buyer of this pay-fixed swaption will exercise it. Conversely, if the five-year swap rate is below 6%, the pay-fixed swaption will expire worthless. The principle is the same for a receive swaption, only in reverse.

Next, we consider the impact of a change in the yield-curve's shape on swaption values. In particular, we will discuss the impact of a steepening and an inverting yield-curve. If the yield-curve steepens, the value of a pay-fixed swaption increases, and the value of a receive-fixed swaption decreases. The intuition is straightforward. A steepening yield-curve indicates that the implied forward rates are increasing at a faster rate than suggested by the initial yield-curve. The higher rates indicate that the floating-rate cash-flows of the underlying swap contract are going to be higher than previously expected. This effect works to the advantage of the pay-fixed swaption buyer because she will receive higher floating-rate cash-flows if the swaption is exercised. The opposite is true for a receive-fixed swaption buyer. By analogous reasoning, an inverted yield-curve indicates that the implied forward rates are decreasing. If this occurs, the value of a pay-fixed swaption decreases, and the value of a receive-fixed swaption increases.

Volatility

There is a positive relationship between swaption values and the assumed interest-rate volatility. If interest volatility increases, all else held constant, chances are greater that underlying swap's value will move in a favorable direction (i.e., higher floating-rate cash-flows for the pay-fixed swaption and higher fixed-rate cash-flows for the receive-fixed swaption). Vega measures the impact of a change in interest-rate volatility on an option's value. For a swaption, vega tells us the sensitivity of the swaption's value (in basis points) to a 1% change in the assumed interest-rate volatility.

A market convention for calculating implied volatility is to use the Black pricing model for options on commodity futures for translating the price of option-type interest rate derivatives into implied volatility. Most market participants use implied volatility of swaption contracts as their estimate of interest-rate volatility. What is the meaning of an "implied yield volatility of, say, 25%?" To interpret this number, one needs to be cognizant that it is derived from the observed option price based on the Black model. As a result, the meaning of it not only depends on the assumption that the market correctly prices the option, but also the fact that the market prices the option in accordance with the Black model.

Given these assumptions, one may interpret that the option market expects a *constant* annualized yield volatility of 25% for the underlying instrument to the maturity date of the option.

Two major assumptions of the Black model are problematic. First, interest rates are assumed to be constant. Yet, the assumption is used to derive the pricing formula for the option, which derives its payoff precisely from the fact that future interest rates (forward rates) are stochastic. The Black model implies a time evolution path for the term structure that leads to the presence of arbitrage opportunities. In other words, the model itself implicitly violates the no-arbitrage spirit in derivatives pricing.

Second, volatilities of futures prices, or forward interest rates, are assumed to be constant over the life of the contract. This assumption runs counter to the empirical record as well as intuition. For example, a forward contract with one month to maturity is more sensitive to changes in the current term structure than a forward contract with one year to maturity. Accordingly, the volatility of the forward rate is inversely related to the time to maturity.

Strike Rate

The value of a swaption is essentially the difference between the strike rate and prevailing swap rate at the time it is being valued. At expiration, a pay-fixed swaption is only exercised when the swap rate is higher than the strike rate. Conversely, at expiration, a receive-fixed swaption is only exercised when the swap rate is lower than the strike rate. Given this backdrop, it is apparent that as the strike rate changes, a pay-fixed swaption and a receive-fixed swaption will behave in an opposite manner. An increase in the strike rate, all else equal, will decrease the value of a pay-fixed swaption and increase the value of a receive-fixed swaption. The reasoning is as follows: As the strike rate increases, the pay-fixed swaption buyer will pay higher fixed-rate cash-flows over the swap's life if the swaption is exercised. This is obviously less valuable than paying a lower fixed-rate for the same floating-rate cash-flows in return. For the receive-fixed swaption buyer, an increase in the strike rate means that the receive-fixed swaption buyer will receive higher fixed-rate cash-flows over the swap's life if the swaption is exercised. For decreases in the strike rate, the effects are reversed.

Time to Expiration

For most options (calls and puts) traded in the financial markets, increasing the option's time to expiration makes it more valuable. This is not the case for swaptions. Increasing a swaption's time to expiration can either increase or decrease its value. This ambiguity is due to the interaction of increasing the time to expiration and the other variables that drive a swaption's value—the current yield-curve, volatility, and the strike rate.

KEY POINTS

- An interest-rate swap is an agreement between two parties to exchange interest payments at designated times in the future based on a notional principal amount.
- In a generic interest-rate swap, one party agrees to make fixed-rate payments and receive floating-rate payments while the counterparty agrees to make floating-rate payments and receive fixed-rate payments.
- The most common reference rate for the floating-rate payments is LIBOR.
- Interest-rate swaps are over-the-counter instruments.
- The default risk in a swap agreement is called *counterparty risk.*
- A swap position can be interpreted as either a package of forward contracts or a package of cash-flows from buying and selling cash market instruments.
- The convention for quoting swap levels is that a swap dealer sets the floating-rate equal to the reference rate and then quotes the fixed-rate that will apply.
- The swap rate is determined by finding the rate that will make the present value of the cash-flow of both sides of the swap equal.
- In a LIBOR-based swap, the cash-flow of the floating-rate side is determined from the Eurodollar futures contract.
- The discount rates used to calculate the present value of the cash-flows in a swap are forward rates.
- The value of an existing swap is equal to the difference in the present value of the two payments.
- The swap spread is the spread over the Treasury par curve specified at the initiation of the swap that the fixed-rate payer must pay.
- Non-generic swaps include constant maturity, accreting/amortizing, zero-coupon, LIBOR-in-arrears, basis, margin, off-market, differential, and forward-start swaps.
- The net present value of all cash-flows is the fair price for canceling a swap.
- Swaption are options to establish a position in an interest-rate swap at some future date.
- The key factors that impact a swaption's value are the yield-curve, volatility, strike rate, and time to expiration.

CHAPTER
SIXTY-THREE

THE VALUATION OF INTEREST-RATE SWAPS AND SWAPTIONS

GERALD W. BUETOW, JR., PH.D., CFA

Innealta Capital

BRIAN J. HENDERSON, PH.D., CFA
Assistant Professor of Finance
The George Washington University

An interest-rate swap is an agreement involving two parties who agree to exchange payments at future dates. The cash-flow amounts exchanged in the future are determined by an agreed-upon interest rate and the size, or notional principal, of the agreement. In the most basic interest-rate swap, commonly referred to as a "plain vanilla interest-rate swap," one party agrees to make variable payments that "float" with a short-term rate while the other party makes fixed-rate payments at an agreed-upon fixed-rate.

Swaps are important tools for risk managers, offering a cost-effective means to altering interest rate exposure. This useful tool for controlling interest rates may be customized in a variety of ways. For example, in an amortizing swap the notional principal declines over time. In an accreting swap, the notional principal increases over time. Other swaps, named forward-start swaps, are swap agreements that commence at a specified date in the future. Another variation of the swap agreement is the basis swap that involves the exchange of payments referencing two different interest rates, such as three-month LIBOR and the three-month Treasury bill.

In this chapter, our focus is on more complex swap structures. We assume the reader is familiar with plain vanilla swaps and the traditional valuation method involving the use of implied forward rates from LIBOR futures contracts to value a swap agreement to compute the swap fixed-rate (SFR). In addition to swaps, we cover the valuation of swaptions. A swaption gives its owner the right to enter into a swap agreement at a future time.

Unlike plain vanilla interest-rate swaps, swaptions have cash flows that depend on an interest rate at a future point in time. This feature requires a versatile approach to valuation. The lattice approach to valuation proves useful due to two important features. First, the interest-rate model driving the lattice approach is fit to no-arbitrage conditions, meaning that the pricing fits the arbitrage values for cash flows using forward rates. Second, the interest-rate models behind the

interest-rate lattice incorporate an assumed interest-rate volatility, enabling this approach to handle option-like features.

The balance of the chapter proceeds as follows. We begin by illustrating the lattice approach to valuation with a plain vanilla interest-rate swap. Next, we demonstrate the versatility of the lattice approach through the valuation of forward-start swaps. The chapter proceeds by presenting and pricing swaptions with a focus on the pricing impact of the important parameters (time-to-expiration, strike rate, and volatility). Next, the chapter presents basis swaps and concludes.

SWAP VALUATION USING THE LATTICE APPROACH

The traditional approach to valuing swaps involves obtaining a no-arbitrage value for the swap cash flows by discounting at the implied forward rates. The implied forward rates come from market prices of Eurodollar futures contracts. Unfortunately the traditional approach is not equipped for valuing cash flows that vary depending on interest rates in the future. For this purpose, the lattice model is a useful tool for valuing interest rate derivative instruments such as swaps and swaptions. In contrast to the traditional approach to valuing swaps, the lattice model incorporates the volatility of interest rates to consider how interest rates may change in the future, providing a flexible valuation framework easily adapted to exotic (non–plain vanilla) instruments.

In general, the lattice approach to valuation begins with the construction of the interest-rate lattice.[1] The values on the interest-rate lattice represent possible interest rates in future periods, describing potential evolutions of interest rates through time. After constructing the interest-rate lattice, the swap cash flows are computed at each "node" on the lattice, resulting in the swap cash-flow lattice. The interest rates from the lattice are then used to compute the present value of the possible future cash flows. This process is referred to as *backwardation:* working backward through the tree to discount the expected future cash flows to a present value.

Constructing the interest-rate lattice begins with an interest-rate model to describe the dynamics of interest rates through time. Although many interest-rate models are used by practitioners, the most common models are one-factor models that describe the evolution of the short rate (one period interest rate) through time. The term *one factor* simply means that the short rate is the only interest rate being modeled and it solely determines the *term structure*. An interest-rate model makes important assumptions about the relationship between short-term interest rates and interest-rate volatility, typically measured as the standard deviation.[2] The examples in this chapter employ a version of the Kalotay, Williams, and Fabozzi interest-rate model.[3]

1. The approach employed here applies regardless of whether a lattice (binomial, trinomial), grid (finite differences), or paths (Monte Carlo) are used to generate the evolution of interest rates.
2. The details of term structure modeling are beyond the scope of this chapter.
3. Andrew J. Kalotay, George O. Williams, and Frank J. Fabozzi, "A Model for the Valuation of Bonds with Embedded Options," *Financial Analysts Journal* (May-June 1993), pp. 35–46. See also Chapter 40 in this handbook.

After selecting an interest-rate model to describe the possible evolution of the interest rate through time, it is useful to express that model in a lattice comprising discrete time periods. Each node on the binomial tree represents a possible short rate over that discrete time step. The interest rate may evolve to the next time step by taking two possible values. There are other models allowing for more than two possible rates in each subsequent period; for example, the trinomial model allows for three rates. To avoid complication, we illustrate the lattice valuation procedure using the binomial model. The important feature of the interest-rate models is that they satisfy the "no-arbitrage" condition, meaning the interest rates they produce match the implied spot rates from bond prices. Additionally, interest-rate models incorporate an assumption regarding interest-rate volatility. The volatility of interest rates is a critical component when valuing interest rate contingent claims since the cash flows to the claim are determined by interest rates in the future. We will see later that the volatility assumption has direct effects on the value of swaptions.

To illustrate the lattice model approach to valuation, we begin by pricing a 5-year plain vanilla interest-rate swap with a swap fixed-rate (SFR) of 3%. To simplify the presentation, and without loss of generality, we consider the swap to have semiannual payments instead of quarterly payments.

Exhibit 63–1 presents the interest-rate lattice that will be used in the valuation process. The model is a one-factor model and describes the possible paths of the short rate (one-period interest rate) through time. The current short rate is 0.3850%, and according to the model, the short rate for the next time period will be either 0.7950% or 0.6902%, where each of these values is equally likely. The interest-rate tree has 10 semiannual time periods, covering the five-year tenor of the swap agreement.

The next step in the valuation process is to compute the cash-flow at each node. The swap payments occur in arrears, but are determined at the start of the period. For instance, the first swap payment is determined today, at $t = 0$, and is based on the current short rate of interest. Referring to Exhibit 63–1, the current rate is 0.3850%. At the end of the first period, the swap counterparty making the fixed-rate payment will make a payment of:

$$\text{Fixed-Rate Payment} = \text{SFR} \times \text{NP} \times (\text{Days in Period}/360)$$

where NP is the notional principal and Days in Period is the number of days in the payment period.

To simplify the presentation, we assume semiannual cash flows and that the fraction of the year is 0.5. The other swap counterparty, the floating-rate payer, makes a payment that is equal to:

$$\text{Floating-Rate Payment} = \text{Floating-Rate} \times \text{NP} \times (\text{Days in Period}/360)$$

Since the swap cash flows are typically netted, the swap cash-flow at the end of the period will be:

$$\text{Net Cash-Flow} = (\text{Floating-Rate} - \text{SFR}) \times \text{NP} \times (\text{Days in Period}/360)$$

Note that when the periodic floating-rate is greater than the SFR, the floating-rate payer makes the net cash-flow payment to the fixed-rate payer. Conversely, when the periodic floating-rate is less than the SFR, the fixed-rate payer makes payment of the net cash flow amount to the floating-rate payer. Exhibit 63–2 presents the net cash flows at each node on the lattice in Exhibit 63–1 for the five-year semiannual swap agreement with a SFR of 3% and notional principal of $100. To illustrate the computation, refer to the node on the upper right hand side of the interest-rate lattice in Exhibit 63–1 where the short rate is 9.1446% at time 4.5 years. At that node, the short rate is 9.1446%. Recall the cash-flow is determined at the start of the period but paid in arrears. Thus, the short rate at time 4.5 years determines the cash-flow at $t = 5$ years. The net cash-flow from the swap is:

$$\begin{aligned}\text{Net Cash-Flow} &= (\text{Floating-Rate} - \text{SFR}) \times \text{NP} \times (\text{Days in Period}/360)\\ &= (9.1446\% - 3.0\%) \times 100 \times 0.5 = 3.0723.\end{aligned}$$

The procedure repeats for each node on the tree. Recall that the cash flows to the swap occur in arrears (at the end of the period) but are determined at the beginning of the period based on the interest rate at that time.

At this point in the valuation process, we have used the interest-rate lattice to compute the swap cash flows at each node on the lattice. To arrive at a value for the interest-rate swap, the next step is to construct another lattice referred to as the *cumulative swap valuation lattice*. Each node of the cumulative swap valuation lattice is the present value of the swap cash flows from all nodes on the cash-flow lattice occurring after that time (see Exhibit 63–2) discounted using the rates on the binomial lattice (see Exhibit 63–1). To illustrate the process, refer to the shaded region in the top right portion of Exhibit 63–3. The cumulative swap valuation at the nodes where $t = 4.5$ are the present values of the cash flows at $t = 5$. Note the time reference here – cash flows ($t = 5$) verse present value of cash flows ($t = 4.5$). Since the swap agreement matures at $t = 5$ years, there are no subsequent cash flows to consider. Thus, the values in the shaded region at $t = 4.5$ years are computed as the present values of the $t = 5$ cash flows (see Exhibit 63–3) discounted at the rates in Exhibit 63–1:

$$\begin{aligned}3.0723/(1 + 9.1446\%/2) &= 2.9380\\ 2.4693/(1 + 7.9386\%/2) &= 2.3750\\ 1.9458/(1 + 6.8917\%/2) &= 1.8810.\end{aligned}$$

Working backward to the next time step ($t = 4$) requires discounting the values at $t = 4.5$ plus the arrears cash-flow that take place at $t = 4.5$. At each node, there are two possible values at the next time step and they are equally likely to occur. To illustrate, the values at the shaded $t = 4$ nodes in Exhibit 63–3 are determined as:

$$\begin{aligned}(0.5 \times 2.9380 + 0.5 \times 2.3750 + 2.3104)/(1 + 7.6208\%/2) &= 4.7846\\ (0.5 \times 2.3750 + 0.5 \times 1.8810 + 1.8079)/(1 + 6.6158\%/2) &= 3.8099.\end{aligned}$$

After computing the cumulative swap values at $t = 4$, backwardation continues by computing the values at $t = 3.5$ years. To illustrate, the shaded value in

Exhibit 63–3 at $t = 3.5$ is computed as the present value of the nodes at $t = 4$ plus the arrears cash-flow received at $t = 4$:

$$(0.5 \times 4.7846 + 0.5 \times 3.8099 + 1.7608)/(1 + 6.5216\%/2) = 5.8667.$$

The process continues through each node, arriving finally at the present value of the swap. Referring to Exhibit 63–3, the present value of the swap with $100 notional principal, 3% swap fixed-rate, and 5-year tenor is –1.5892. Recall that we computed the cash flows from the perspective of the fixed-rate payer, meaning that the cash-flow is negative (an outflow) when the floating-rate is less than the swap fixed-rate. Thus, the negative value indicates that the present value of the fixed-rate payments (3% SFR) is greater than the present value of receiving the floating-rate payments. At the time the counterparties enter into a plain vanilla swap, the present value is zero, meaning the SFR can be determined in the lattice model by iterating on the SFR until the present value at $t = 0$ of the cumulative swap valuation line equals zero. In this example, a SFR of 2.6650% results in the initial value of the swap equaling zero, illustrating why the swap value is negative to the fixed-rate payer in the example where the SFR is 3%. Interest rates must have declined since the inception of the SFR 3% plain vanilla swap.

It is important to note that the value of the plain vanilla swap obtained through the lattice model is identical to the value obtained through the traditional valuation method. This equivalence is due to the fact that the interest-rate model is derived through no-arbitrage conditions based on forward rates determined by market data. The key advantage to the lattice approach will be clear in later sections when we value interest-rate swaptions and need to account for volatility in the possible paths of future interest rates.

Now that we have introduced the binomial lattice, we proceed by introducing more complicated swap structures and swaptions.

FORWARD-START SWAPS

A forward start swap is a swap agreement commencing at some specified date in the future. An example is a two-year swap that begins three years from today. We refer to a forward start swap by the date at which the swap begins and the maturity date of the swap using the notation (y_{start}, y_{end}). Thus, the two-year swap beginning three years from today is denoted (3,5). In addition to the start date and maturity date, the forward start swap agreement also specifies the swap fixed-rate and the notional principal. The swap fixed-rate for a forward start swap is referred to as the forward swap fixed-rate.

To illustrate the valuation of a forward start swap, we will use the interest-rate lattice presented in Exhibit 63–1 to value the two-year swap that begins three years from today with a fixed-rate of 3.250% and notional principal of 100. The process begins by calculating the swap cash flows at each node on the interest-rate lattice and then constructing the cumulative valuation lattice through the process outlined in the previous section. Exhibit 63–4 presents the cumulative valuation

lattice for this swap. Note that the swap begins three years from today and the possible values at time $t = 3$ years are highlighted in the lattice.

The cumulative value lattice produces seven possible values for the forward start swap at $t = 3$ years, and these values can be used to determine the value of the swap agreement. At this point, the missing link is the probability of each of the possible lattice values. The probability of reaching any node in the tree is determined by the number of paths through the lattice that arrive at that node. In the binomial lattice, where there are two possible movements for the rate in the next period, the following formula can be used to calculate the number of paths arriving at any given node:

$$\text{Number of Paths} = \frac{n!}{j!(n-j)!},$$

where n is the number of periods and j is the number of down-states. Exhibit 63–5 presents the number of paths arriving at each node. By referring to the paths at time 3 in the tree, we illustrate the computation using the above formula. Since time on the tree at $t = 3$ corresponds to the sixth semiannual time step, $n = 6$. At the very top node, there are no down nodes so $j = 0$. Evaluating the formula, we

find that the number of paths arriving at the top node is 6!/(0!(6!)) = 1 path, which makes sense since the one and only path arriving at the top node consists solely of up-movements. At the node that is second from the top at $t = 3$, the time periods are still 6 but at this node there is one down-step so $j = 1$. Evaluating the formula, there are 6!/(1!(5!)) = 6 possible paths arriving at this node.

To finish the demonstration, we compute the number of nodes at the third node from the top at $t = 3$. At this node, $n = 6$ and there are two down nodes so $j = 2$. Applying the formula, the number of paths arriving at the third node are 6!/(2!(4!)) = 15 paths.

Across the six nodes at $t = 3$, there are a total of 64 possible paths. The probability of arriving at each node is simply the number of paths to that node divided by the number of possible paths arriving at all nodes at this time. The value of the forward start swap is determined by weighting each of the cumulative swap valuation nodes corresponding to the forward start swap start date by the probability of arriving at that node. This calculation is illustrated in Exhibit 63–6, which presents the seven nodes at $t = 3$ and the corresponding cumulative swap valuation from the $t = 3$ node in Exhibit 63–5. The probability of arriving at each node is computed as the number of paths arriving at that node divided by the total number of paths arriving at any node at this time. The product of the cumulative swap valuation and the probability result in the probability weighted value. Summing the probability weighted values results in the forward start swap value. In this case, the value for 100 notional principal of the (3,5) forward start swap with a 3.250% forward start fixed-rate is 1.87089. Note that this is the value to the fixed-rate payer. Recall that we computed the cash flows at each node as the rate on the interest-rate lattice minus the swap fixed-rate. Thus, the positive value indicates

EXHIBIT 63–6

that the value of the floating-rate payments exceeds the value of the fixed-rate payments, implying a positive value to the fixed-rate payer. The value to this swap for the floating-rate swap payer is the negative of this amount, –1.87089. The SFR that would produce an FSS value of zero is 4.233% and is computed in the same manner as the iterative routine used to compute the SFR of a zero value plain vanilla swap.

Once we understand the process, we can value forward-start swaps with the same SFR that begin at each node on the lattice and end at five years. That is to say we may compute the values of the otherwise identical (0,5), (0.5,5), (1,5), (1.5,5), (2,5), (2.5,5), (3.5,5), (4,5), and (4.5,5) swaps. Exhibit 63–7 illustrates the computation of forward start swap values at each time period on the lattice.

VALUING SWAPTIONS

A swaption is an option contract on an interest-rate swap. The owner of a swaption has the right to initiate a swap agreement on or by a specified future date. The swaption specifies several important features of the swap, including the tenor of the swap and the swap fixed-rate. The swap fixed-rate is the strike rate for the option. Unlike a forward start swap, where both counterparties have the obligation to participate in the swap, the swaption owner has the right, but not the obligation, to enter into the swap. We will demonstrate the valuation procedure for swaptions using the interest-rate lattice and discuss how the important parameters affect the swaption valuation.

A payer's swaption (a pay fixed swaption) gives the owner the right to enter into an interest-rate swap as the fixed-rate payer and receive floating-rate payments. Swaptions may be either European or American style. The difference is that the owner of a European style swaption may exercise their right to enter into the swap at the expiration of the swaption, while the owner of an American style swaption may exercise that right any time up to the expiration date. For our purposes, we will consider European style swaptions.

A receiver's swaption (receive fixed swaption) givers the owner the right to enter into an interest-rate swap as the floating-rate payer and fixed-rate receiver. As an example, consider a swaption with a fixed-rate of 3.650%, option expiration date of two years, and the swap tenor is three years. The buyer of this swaption has the right at the end of two years to enter into a swap in which they make floating-rate payments and receive fixed-rate payments of 3.650%. We introduce the notation ($y_{expiration}$, y_{tenor}) for swaptions to refer to the expiration date of the swaption and the tenor of the swap. Thus, the receiver's swap is a (2,3) swaption.

To illustrate swaption pricing, we will price several payers' swaps with a strike rate of 3.650%. The lattice approach is helpful to value swaptions, and the valuation example uses the interest-rate lattice from Exhibit 63–1. After constructing the interest-rate lattice, the next step in the valuation process is to construct the pay fixed cash-flow lattice for a plain vanilla swap with a notional

principal of $100, based on a swap fixed-rate of 3.650%. Recall that at each node on the lattice, the cash-flow is determined by the swap fixed-rate, the notional principal, the corresponding node on the interest-rate lattice:

$$\text{Cash-Flow}_{i,j} = (F_{i,j-1} - SFR) \times NP_j \times 0.5$$

where $F_{i,j-1}$ is the floating-rate at node (i,j-1), indicating the arrears cash-flow at time j. Exhibit 63–8 presents the cash-flow lattice for the plain vanilla swap with a strike rate of 3.650%. To illustrate the computation of the cash flows, refer to the top-right node on the tree. Note that this cash-flow occurs at time $t = 5$, but is determined by the rate at $t = 4.5$. The corresponding rate from the interest-rate lattice is 9.1446%, so the cash-flow at this node is:

$$\text{Cash-Flow}_{1,5} = (9.1446\% - 3.650\%) \times 100 \times 0.5 = 2.7473$$

After constructing the cash-flow lattice in Exhibit 63–8, the next step in the swaption valuation process is to construct the cumulative swap valuation lattice for the plain vanilla pay-fixed swaption. Exhibit 63–9 presents the cumulative valuation lattice. The cumulative swap valuation lattice can then be used to value pay fixed swaptions.

To illustrate the swaption valuation, we price the (3,2) pay fixed swaption, as illustrated in Exhibit 63–10. The option expires in year 3 and the values corresponding to expiration are referred to as the expiration values. The expiration value at each node (here $t = 3$) come from the values in the cumulative valuation lattice (see Exhibit 63–9). Recall that the swaption gives the owner the right, but not the obligation to enter into the pay fixed swap. The owner will only exercise this right when the value of the two-year swap commencing at $t = 3$ is positive. Thus, the expiration values for the swaption are the maximum of zero or the value at the corresponding node on the cumulative valuation lattice. To illustrate, at the bottom node on the tree at $t = 3$, the cumulative valuation for the pay-fixed swap is –0.7711. Intuitively, this makes sense since the bottom nodes correspond to low interest rates that adversely affect the fixed-rate payer.

After determining the expiration values for the swaption, the remaining portion of the lattice is populated using backward induction. The corresponding rates from the interest-rate lattice determine the discount factors. To illustrate the process, the top value at year 2.5 in Exhibit 63–10 is computed as:

$$0.5\ (5.058457 + 3.537322)/(1 + 4.4031\%/2) = 4.205307$$

Repeating this process throughout the lattice in Exhibit 63–10 results in a value of $1.170195 for the (3,2) pay fixed swaption per $100 of notional principal. It is worth noting that the lattice valuation process requires as inputs the interest-rate lattice and the swaps valuation lattice. Once these have been determined, it is straightforward to price any variation of the swaption having the same fixed-rate. The lattice valuation framework is very flexible and handles easily any adjustments such as varying the notional principal (amortizing or accreting). This flexibility makes the lattice approach to valuation attractive.

VALUING BASIS SWAPS AND NON-LIBOR-BASED SWAPS

To this point, we have focused on the valuation of swap structures involving the exchange of floating and fixed-rate payments in which the floating leg of the swap is based off LIBOR. Next, we generalize our discussion to include swaps in which both legs of the swap float and to swap structures based on interest rates other than LIBOR.

A basis swap is a swap agreement in which both legs of the swap are based on different rates. For example, the spread between the 90-day Treasury bill rate and the three-month LIBOR is referred to as the *TED spread*. In a LIBOR TED swap, one counterparty makes payments based on LIBOR and receives payments based on the 90-day Treasury bill rate plus a spread. This is referred to as a *pay LIBOR TED swap*.

We illustrate the lattice approach to valuation for a one-year pay LIBOR TED swap with a *Spread* of 0.376%. Since each leg of the swap references a floating-rate, the lattice approach requires a lattice for each rate. Exhibit 63–11 presents the one-year interest-rate lattices for LIBOR and the 90-day Treasury bill rate. Note that we assume a 10% volatility for LIBOR and 7.5% for the Treasury bill rate. In previous examples, we assumed semiannual periodicity for payments. In this example we assume quarterly.

After the two interest-rate lattices are in place, the next step in the valuation process is to compute the cash flows for the pay LIBOR TED swap. Each cash-flow at node i in period j is computed as follows. Note that in the example

we ignore the exact day count and assume each period is exactly one quarter of the year.

$$CF_{i,j} = (\text{T-Bill}_{i,j-1} + \text{Spread} - \text{LIBOR}_{i,j-1}) \times 0.25 \times NP_j$$

It is important to point out that the *Spread* is the adjustment to the Treasury bill rate such that the present values of the two payment streams are equal. To obtain the spread that equates the two cash-flow streams, we can iterate on the *Spread* value.

Following the two interest-rate lattices in Exhibit 63–11, the next step is the computation of the pay LIBOR TED swap cash flow at each node on the tree. To illustrate, consider the highest node on the tree at maturity of the swap. Referring to Exhibit 63–11, the LIBOR and Treasury bill rate at this node are 1.01% and 0.29%, respectively. Using the *Spread* of 0.376%, the payment on $100 notional principal is:

$$\begin{aligned} CF_{i,j} &= (\text{T-Bill}_{i,j-1} + \text{Spread} - \text{LIBOR}_{i,j-1}) \times 0.25 \times NP_j \\ &= (0.29\% + 0.376\% - 1.01\%) \times 0.25 \times NP_j \\ &= -0.085 \end{aligned}$$

The cash flows for the swap at all times are presented in Exhibit 63–12. After constructing the cash flows, the final step for valuing the pay LIBOR TED swap is to compute the cumulative value lattice. This procedure is exactly the same as demonstrated in previous sections. The values are presented in Exhibit 63–13. Note that the present value of the expected payments is zero, indicating that the spread of 0.376% produces zero value for the swap. This means the present value of the LIBOR and the Treasury bill plus *spread* legs are identical. For Spreads greater (smaller) than 0.376%, in this example the pay LIBOR TED swap would have positive (negative) present value. To note the flexibility of the lattice approach to valuation, note that it is straightforward to extend the valuation for a swaption on a basis swap following the procedure outlined in the previous section.

FACTORS AFFECTING SWAP VALUATION

The flexibility of the lattice approach to valuation facilitates the analysis of a swaption's sensitivity to changes in the swaption terms and changes in market inputs such as volatility. In this section, we illustrate the sensitivity of swaption valuations to interest-rate volatility and the strike rate.

There are two main determinants of the values in the interest-rate lattice: the current term structure and interest-rate volatility. Recall that the interest-rate lattice is the basic building block in the lattice approach to valuing swaptions. Changing the expiration date of a swap changes the value of the swaption, but the directional change in value depends on the current term structure, volatility, and strike price. Interest-rate volatility, however, increases the value of swaptions, holding all else constant.

The chart in Exhibit 63–14 illustrates the effect of interest-rate volatility and the expiration of the swap on the valuation of four different pay fixed swaptions. To construct the example, we use the LIBOR interest-rate lattice from Exhibit 63–1 and consider pay-fixed swaptions each having a strike rate equal to 3.5%. In the figure, there is not a monotonic relation between the swaption expiration and value. Each swaption's value, however, does increase as volatility increases.

We next consider the joint effect of the strike rate and interest-rate volatility on interest-rate swaptions. Exhibit 63–14 illustrates that swaption values increase as interest-rate volatility increases, holding all else constant. The strike rate has an important impact on the value of the swaption. For a pay

EXHIBIT 63–14

Pay Fixed Swaption Values and Volatility, Strike Rate = 3.5%

fixed swaption, in which the option owner has the right to enter into a swap agreement where they pay the fixed-rate and receive floating payments, as the strike rate increases, the value of the pay fixed swaption declines since the value of the fixed-rate payments rises relative to the floating-rate payments that party will receive. Conversely, in a receive fixed swaption, in which the option owner has the right to enter into a swap agreement where they receive fixed-rate payments and make floating-rate payments, the value of that right increases as the strike rate increases.

Exhibit 63–15 illustrates the joint effect of the strike rate and interest-rate volatility on the value of a (2,3) pay fixed swaption. The surface plot of the swaption value is increasing in the volatility (at higher levels of volatility, the swaption's value is greater), and decreasing in the strike rate (at lower strike rates, the pay-fixed swaption's value is greater). Exhibit 63–16 illustrates the receive fixed swaption value across strike rates and levels of volatility. It is important to note that, across the strike rate dimension, the graph in Exhibit 63–16 is the mirror image of Exhibit 63–15, demonstrating that strike rate has the opposite impact on the values of receive fixed swaptions as it has on pay fixed options. The value of the receiver's swaption, is positively related to the level of volatility, in which the receiver's swaption increases in value as the assumed lever of interest-rate volatility increases.

EXHIBIT 63–15

The Effect of Strike Rate and Interest-Rate Volatility on the (2,3) Pay Fixed Value

EXHIBIT 63–16

The Effect of Strike Rate and Interest-Rate Volatility on the (2,3) Receive Fixed Swaption Value

KEY POINTS

- Interest-rate swap agreements involve two parties agreeing to exchange payments in the future at agreed-upon terms.
- Exotic swap agreements are customized contracts. Common variations include forward-start swaps, amortizing notional principal swaps, accreting notional principal swaps, basis swaps, and non-LIBOR swaps.
- Swaptions are option contracts in which the owner has the right, but not the obligation, to enter into a swap agreement in the future.
- The lattice approach to swap and swaption valuation is a powerful, flexible valuation framework easily adapted to handle variations of exotic swaps.
- Swaption values are determined by market inputs such as the term structure of interest rates and interest-rate volatility in addition to contract specifications such as tenor and strike rate. Holding all else constant, volatility increases swaption values. Holding all else constant, increasing the strike rate decreases the value of a pay-fixed swaption but increases the value of a receive-fixed contract.

CHAPTER
SIXTY-FOUR

THE BASICS OF INTEREST-RATE OPTIONS

WILLIAM J. GARTLAND, CFA
Managing Director
Benchmark Solutions

NICHOLAS C. LETICA
Managing Director
Citigroup Global Markets, Inc.

As the sophistication and diversity of investors have grown, the need for derivative instruments such as options has increased accordingly. Knowledge of option strategies, once the province of a few speculators, is now necessary for everyone who wishes to maintain a competitive edge in an increasingly technical market. Moreover, options technology has been applied with increasing success to securities with optionlike characteristics such as callable bonds and mortgage-backed securities.

In Chapter 59, option contracts were described: exchange-traded options on physical securities, exchange-traded options on futures, and over-the-counter (OTC) options. In this chapter we will review how options work, their risk/return profiles, the basic principles of option pricing, and some common trading and portfolio. A more detailed discussion of hedging strategies is provided in Chapter 61.

Throughout most of the discussion, our focus will be on options on physicals. The principles, however, are equally applicable to options on futures or futures options.

HOW OPTIONS WORK

An *option* is the right but not the obligation to buy or to sell a security at a fixed price. The right to buy is called a *call,* and the right to sell is called a *put;* a call makes money if prices rise and a put makes money if prices fall.

If the owner of an option uses the option to buy or to sell the underlying security, we say that the option has been *exercised.* Because the holder is never required to exercise an option, the holder can never lose more than the purchase price of the option—an option is a limited-liability instrument.

An option on a given security can be specified by giving its strike price and its expiration date. The *strike price* is the price on the optional purchase. For example,

a call with a strike price of par is the right to buy that security at par. The *expiration date* is the last date on which the option can be exercised: after that, it is worthless, even if it had value on the expiration date. If an option is allowed to expire, it is said to be *terminated.* On or before the expiration date, the option holder may decide to sell the option for its market value. This is called a *pair-off.*

Some options can be exercised at any time until expiration: they are called *American* options. On the other hand, some options can only be exercised at expiration and are called *European* options. Because it is always possible to delay the exercise of an American option until expiration, an American option is always worth at least as much as its European counterpart. In practice, there are only a limited number of circumstances under which early exercise is advantageous, so the American option rarely costs significantly more than the European.

The easiest way to analyze a position in a security and options on that security is with a *profit/loss graph.* A profit/loss graph shows the change in a position's value between the *analysis date* ("now") and a *horizon date* for a range of security prices at the horizon.

Suppose that a call option struck at par is bought today for 1 point. At expiration, if the security is priced below par, the option will be allowed to expire worthless; the position has lost 1 point. If the security is above par at expiration, the option will be exercised; the position has made 1 point for every point the security is above par, less the initial one-point cost of the option. Exhibit 64–1 shows the resulting profit/loss graph.

EXHIBIT 64–1

Long Call versus Underlying Security Price
Call Struck at Par, at Expiration, with 1-Point Premium

EXHIBIT 64–2

Long Put versus Underlying Security Price
Put Struck at Par, at Expiration, with 1-Point Premium

Note that if the price of the underlying increases by 1 point, the option purchase breaks even. This happens because the value of the option at expiration is equal to the initial purchase price. A price of 101 is the break-even price for the call: the call purchase will make money if the price of the underlying exceeds 101 at expiration.

A put is the reverse of a call. Look at Exhibit 64–2, which is the profit/loss graph of a put option struck at par bought for 1 point. At expiration, the put is worth nothing if the security's price is more than the strike price and is worth one point for every point that the security is priced below the strike price. The break-even price for this trade is 99, so the put purchase makes money if the underlying is priced below 99 at expiration.

Put-Call Parity

A put and a call struck at-the-money split up the profit/loss diagram of the underlying security into two parts. Consider the position created by buying a call and selling a put such that the strike price of the two options is equal to the price of the underlying. If the price of the security goes up, the call will be exercised; if the price of the security goes down, the put will be exercised. In either case, at expiration the underlying is delivered at the strike price. Thus, in terms of profit and loss, owning the call and selling the put are the same as owning the underlying.

Exhibit 64–3 divides the profit/loss graph of the underlying security into graphs for a long call and a short put, respectively. The following three facts

EXHIBIT 64–3

Long Security = Long Call + Short Put

can be deduced:

Long security = long call + short put (Exhibit 64–3)

Long call = long security + long put (Exhibit 64–4)

Long put = short security + long call (Exhibit 64–5)

This relationship is called *put-call parity;* it is one of the foundations of the options markets. Using these facts, a call can be created from a put by buying the underlying, or a put made from a call by selling the underlying. This ability to convert between puts and calls at will is essential to the management of an options position.

Valuing an Option

The first fact to determine about an option is its worth. There are many option valuation models for each class of options, each of which uses different parameters and returns slightly different values. However, the five main determinants of option value are the price of the underlying, the strike price of the option, the expiration of the option, the volatility of the underlying, and the cost of financing the underlying.

The most apparent component of option value is intrinsic value. The *intrinsic value* of an option is its value if it were exercised immediately. An option with

EXHIBIT 64–4

Long Call = Long Security + Long Put

intrinsic value is an *in-the-money* option. When the underlying security trades right at the strike price, the option is called *at-the-money.* Otherwise, an option with no intrinsic value is called *out-of-the-money.*

An option may have value over and above its intrinsic value, called *time value.* The intrinsic value is the value of the option if exercised immediately, whereas the time value is the remaining value in the option due to time expiration. Clearly, the more time there is to expiration, the greater is the time value.

Exhibit 64–6 graphs the value of an option as time to expiration increases. Exhibit 64–7 compares the value of an option at expiration with the values of options with one and three months to expiration. There is a sharp corner in the graph at the strike price that becomes more pronounced as the time to expiration decreases. This sharp corner makes an at-the-money option increasingly difficult to hedge as expiration approaches.

If the option is out-of-the-money, it has some time value because there is a chance that the option will expire in-the-money; as it gets further out-of-the-money, this is less likely and the time value decreases.

If the option is in-the-money, its time value is due to the fact that it is better to hold the option than the corresponding position in the underlying security because if the security trades out-of-the-money the potential loss on the option is

EXHIBIT 64–5

Long Put = Short Security + Long Call

EXHIBIT 64–6

Call Option Value versus Time until Expiration
Three Calls: At-the-Money, 1 Point In-the-Money, 1 Point Out-of-the-Money

EXHIBIT 64–7

Call Option Value versus Underlying Security Price
Call Struck at Par with One and Three Months to Expiration

limited to the value of the option; as the option gets further in-the-money, this possibility becomes more farfetched and the time value decreases.

Either way, the time value depends on the probability that the security will trade through the strike price. In turn, this probability depends on how far from the strike price the security is trading and how much the security price is expected to vary until expiration.

Volatility measures the variability of the price or the yield of a security. It measures only the magnitude of the moves, not the direction. Standard option pricing models make no assumptions about the future direction of prices but only about the distribution of these prices. Volatility is the ideal parameter for option pricing because it measures how wide this distribution will be. We discuss volatility in more detail at the end of this chapter.

The higher the volatility of a security, the higher is the price of options on that security. If a security had no volatility, for example, that security would always have the same price at time of purchase of an option as at its expiration, so all options would be priced at their intrinsic value. Increasing the volatility of a security increases the time value of options on that security as the chance of the security price moving through the strike price increases. Increases in the value of an at-the-money option are approximately proportional to increases in the volatility of the underlying. Exhibit 64–8 shows how the price of an option behaves as the volatility of the underlying security increases.

EXHIBIT 64–8

Call Option Value versus Percent Price Volatility
Three Calls: At-the-Money, 1 Point In-the-Money, 1 Point Out-of-the-Money; Three Months from Expiration

The final factor that influences options prices is the *carry* on the underlying security. Carry is the difference between the value of the coupon payments on a security and the cost of financing that security's purchase price. With the usual upward-sloping yield-curve, most securities have a positive carry.

The effect of the carry can be seen by comparing the price of an at-the-money call with an at-the-money put where the underlying security has a positive carry. The writer of the call anticipates the chance of being required to deliver the securities and thus buys the underlying as a hedge; the put writer hedges by selling the underlying. The call writer earns the carry while the put writer loses the carry, so the call should cost less than the put. When the yield-curve inverts and short-term rates are higher than long-term rates, carry becomes negative and calls cost more than puts.

By put-call parity, selling an at-the-money call and buying an at-the-money put are equivalent to shorting the underlying security. The cash taken out of the option trade, accounting for transaction costs, compensates the option holder for the carry on the position in the underlying until expiration. This trade is called a *conversion,* and it is used frequently to obtain the effect of a purchase or sale of securities when buying or selling the underlying is impossible for accounting reasons.

Exhibit 64–9 compares the cost of an at-the-money call and put for a range of financing rates. The two graphs intersect where the call and the put have the same value: this happens when the cost of financing the underlying is equal to the coupon

EXHIBIT 64–9

Treasury Option Value versus Financing Rate
Long Call, Long Put Struck at Par, Three Months to Expiration

yield on the security, so the carry is zero and there is no advantage to holding the underlying over shorting it.

Exhibit 64–10 summarizes the parameters that affect the value of an option and how much raising each parameter affects that value.

Delta, Gamma, and Theta: Hedging an Option Position

More precise quantitative ways to describe the behavior of an option are needed to manage an option position. Options traders have created the concepts of delta,

EXHIBIT 64–10

The Effect of an Increase of a Factor on Option Values

	Call	Put
Underlying price	Increase	Decrease
Strike price	Decrease	Increase
Carry	Decrease	Increase
Time to expiration	Increase	Increase
Volatility	Increase	Increase

gamma, and theta for this purpose. Delta measures the price sensitivity of an option, gamma the convexity of the option, and theta the change in the value of the option over time.

For a given option, the *delta* is the ratio of changes in the value of the option to changes in the value of the underlying for small changes in the underlying. A typical at-the-money call option would have a delta of 0.5; that means for a 1-cent increase in the price of the underlying the value of the call would increase by 0.5 cents. On the other hand, an at-the-money put would have a delta of –0.5; puts have negative deltas because they decrease in value as the price of the underlying increases (see Exhibit 64–10).

The standard method of hedging an options position is called *delta hedging,* which unsurprisingly makes heavy use of the delta. The idea behind delta hedging is that for small price moves, the price of an option changes in proportion with the change in price of the underlying, so the underlying can be used to hedge the option. For example, 1,000,000 calls with a delta of 0.25 would for small price movements track a position of 250,000 of the underlying bonds, so a position consisting of 1,000,000 of these long calls and 250,000 of the security sold short would be delta-hedged. The total delta of a position shows how much that position is long or short. In the preceding example, the total delta is

$$0.25 \times 1{,}000{,}000 - 1 \times 250{,}000 = 0$$

so the position is neither long nor short.

Intuitively, the delta of an option is the number of bonds that are expected to be delivered into this option. For example, an at-the-money call has a delta of 0.5, which means that one bond is expected to be delivered for every two calls that are held. In other words, an at-the-money call is equally as likely to be exercised as not. An option that is deeply out-of-the-money will have a delta that is close to 0 because there is almost no chance that the option will ever be exercised. An option that is deeply in-the-money almost certainly will be exercised. This means that a deeply in-the-money put has a delta of –1 because it is almost certain that the holder of the option will exercise the put and deliver one bond to the put writer.

Put-call parity tells us that a position in the underlying security may be duplicated by buying a call and selling a put with the same strike price and expiration date. Thus the delta of the call less the delta of the put should be the delta of the underlying. The delta for the underlying is 1, so we get the following equation:

$$\text{Delta}(\textit{call}) - \text{delta}(\textit{put}) = 1$$

where call and put are options on the same security with the same strike price and expiration date. This says that once the call is bought and the put sold, the bond is certain to be delivered; if the call is out-of-the-money, the put is in-the-money. Moreover, as the chance of having the underlying delivered into the call becomes smaller, the chance of having to accept delivery as the put is exercised becomes larger. Exhibit 64–11 compares the deltas for a long and a short put.

Making the position delta-neutral does not solve all hedging problems, however. This is demonstrated in Exhibit 64–12. Each of the three positions

EXHIBIT 64–11

Option Delta versus Underlying Security Price
Long Call, Short Put Struck at Par, Three Months to Expiration

shown is delta-neutral, but position 1 is clearly preferable to position 2, which is, in turn, better than position 3. The difference between these three positions is *convexity*. A position such as position 1 with a profit/loss graph that curves upward has a positive convexity, whereas position 3 has a graph that curves downward and thus has negative convexity.

Gamma measures convexity for options; it is the change in the delta for small changes in the price of the underlying. If a position has a positive gamma, then as the market goes up the delta of the position increases and as it declines the delta increases. Such a position becomes longer as the market trades up and shorter as the market trades down. A position like this is called *long convexity* or *long volatility.* These names come from the fact that if the market moves in either direction this position will outperform a position with the same delta and a lower gamma. Exhibit 64–13 shows this phenomenon.

A long option always has a positive gamma. The delta of a call increases from 0 to 1 as the security trades up, and the delta of a put increases also, moving from −1 to 0. Exhibits 64–1 and 64–2 show that the profit/loss graph of options curves upward. Because of this, options traders often speak of buying or selling volatility as a synonym for buying or selling options.

A position with a zero gamma is called *flat convexity* or *flat gamma.* Here, a change in the underlying security price does not change the delta of the position. Such a position trades like a position in the underlying with no options bought or sold. If the position has in addition a delta of zero, then its value is not affected by

EXHIBIT 64–12

Delta-Neutral Positions with Different Gamma

EXHIBIT 64–13

Profit/Loss Diagram with Convexity
Long Security with Flat and Long Convexity

small changes in the price of the underlying security in either direction. Position 2 in Exhibit 64–12 is a profit/loss graph for a position with no delta or gamma.

A position with negative gamma is called *short volatility* or *short convexity.* The profit/loss curve slopes downward in either direction from the current price on the underlying; thus the position gets longer as the market trades down and shorter as the market trades up. Either way, this position loses money if there are significant price movements. Position 3 demonstrates this behavior.

A position that is long volatility is clearly preferable to an otherwise identical position that is short volatility. The holder of the short-volatility position must be compensated for this. In order to create a position that is long volatility it is necessary to purchase options and spend money; moreover, if the market does not move, the values of the options will decrease as their time to expiration decreases, so the position loses money in a flat market.

Conversely, creating a position that is short volatility involves selling options and taking in cash. As time passes, the value of these options sold decreases because their time value falls, so the position makes money in a flat market. Large losses could be sustained in a volatile market, however.

To describe the time behavior of options, there is one last measure called *theta.* The theta of an option is the overnight change in value of the option if all other parameters (prices, volatilities) stay constant. This means that a long option has a negative theta because as expiration approaches, the time value of the option will erode to zero. For example, a 90-day at-the-money call that costs 2 points might have a theta of –0.45 ticks per day.

Exhibit 64–14 shows the effects of different volatility exposures.

EXHIBIT 64–14

Comparison of Different Volatility Positions (All Positions Are Delta-Neutral)

	Short Volatility	Flat Volatility	Long Volatility
Convexity	Position has negative convexity: gamma < 0	Position has no convexity: gamma = 0	Position has positive convexity: gamma > 0
Options purchased	More sold than bought	Sold as many as bought	More bought than sold
Time value	Position earns value as time passes: theta > 0	Position stays flat as time passes: theta = 0	Position loses value as time passes: theta < 0
Market moves	Position loses money if the market moves in either direction	Position is invariant with respect to market moves	Position makes money if the market moves in either direction

OPTIONS STRATEGIES—REORGANIZING THE PROFIT/LOSS GRAPH

Investors have many different goals: reducing risk, increasing rates of return, or capturing gains under expected market moves. Often these objectives are simply to rearrange the profit/loss graph of a position in accordance with the investor's expectations or desires. By increasing the minimum value of this graph, for example, the investor reduces risk.

Options provide a precise tool to accomplish this rearrangement. Because it is impossible to replicate the performance of an option position using just the underlying, options allow a much broader range of strategies to be used. The following characteristics of options provide an explanation.

Directionality

Both a put and a call are directional instruments. A put, for example, performs only in a decreasing market. This property makes options ideal for reducing directional risk on a position. Take, for example, a position that suffers large losses in a downward market and makes a consistent profit if prices rise. By purchasing a put option, some of these profits are given up in exchange for dramatically increased performance if the market declines.

Convexity

Buying and selling options makes it possible to adjust the convexity of a position in almost any fashion. Because OTC options can be purchased for any strike price and expiration, convexity can be bought or sold at any place in the profit/loss graph. For example, an investor holding mortgage-backed securities priced just over par might anticipate that prepayments on this security would start to increase dramatically if the market traded up, attenuating possible price gains. In other words, the investor feels that the position is short convexity above the market. To adjust the profit/loss graph, calls could be purchased with strike prices at or above the market. This trade sells some of the spread over Treasuries in exchange for increased performance in a rising market.

Fee Income

An investor who wishes to increase the performance of a position in a stable market can sell convexity by writing options and taking in fees. This increases the current yield of the position, at the cost of increasing volatility risk in some area of the profit/loss graph. A typical example of this is the venerable covered call strategy, where the manager of a portfolio sells calls on a portion of the portfolio, forgoing some profits in a rising market in exchange for a greater return in a stable or decreasing market.

Leveraged Speculation

Investors with a higher risk/reward profile wish to increase their upside potential and are willing to accept a greater downside risk. In this case, options can be used as a highly leveraged position to capture windfall profits under a very specific market move. A strongly bullish investor might purchase 1-point out-of-the-money calls with 30 days to expiration for 1/2 point. If the market traded up 2 points by expiration, the option then would be worth 1 point, and the investor would have doubled the initial investment; a corresponding position in the underlying would have appreciated in value by only about 2%. Of course, if the market did not trade up by at least 1 point, the calls would expire worthless.

CLASSIC OPTION STRATEGIES

This section gives a brief explanation of some of the simplest pure options strategies.

Straddle

The most pure convexity trade is called a *straddle,* composed of one call and one put with the same strike price. Exhibit 64–15 shows the profit/loss graph of a straddle struck at-the-money at expiration and with three months to expiration.

EXHIBIT 64–15

Profit/Loss Diagram for a Long Straddle
Struck at Par, at Expiration, and Three Months Out

This position is delta-neutral because it implies no market bias. If the market stays flat, the position loses money as the options' time value disappears by expiration. If the market moves in either direction, however, either the put or the call will end up in-the-money, and the position will make money. This strategy is most useful for buying convexity at a specific strike price. Investors who are bearish on volatility and anticipate a flat market could sell straddles and make money from time value.

Strangle

A *strangle* is the more heavily leveraged cousin of a straddle. An at-the-money strangle is composed of an out-of-the-money call and an out-of-the-money put. The options are struck so that they are both equally out-of-the-money, and the current price of the security is halfway between the two strikes. The profit/loss graph is found in Exhibit 64–16.

Just like a straddle, a strangle is a pure volatility trade. If the market stays flat, the position loses time value, whereas if the market moves dramatically in either direction the position makes money from either the call or the put. Because the options in this position are both out-of-the-money, the market has to move significantly before either option moves into the money. The options are much cheaper, however, so it is possible to buy many more options for the same money.

EXHIBIT 64–16

Profit/Loss Diagram for a Long Strangle
Struck at Par, at Expiration, and Three Months Out

This is the ideal position for the investor who is heavily bullish on volatility and wants windfall profits in a rapidly moving market.

Writing strangles is a very risky business. Most of the time the market will not move enough to put either option much into the money, and the writer of the strangle will make the fee income. Occasionally, however, the market will plummet or spike, and the writer of the strangle will suffer catastrophic losses. This accounts for the picturesque name of this trade.

Spread Trades

Spread trades involve buying one option and funding all or part of this purchase by selling another. A *bull spread* can be created by owning the underlying security, buying a put struck below the current price, and selling a call above the current price. Because both options are out-of-the-money, it is possible to arrange the strikes so that the cost of the put is equal to the fee for the call. If the security price falls below the put strike or rises above the call strike, the appropriate option will be exercised and the security will be sold. Otherwise, any profit or loss will just be that of the underlying security. In other words, this position is analogous to owning the underlying security except that the final value of the position at expiration is forced to be between the two strikes. Exhibit 64–17 shows the profit/loss graph of this position at expiration and with three months left of time value.

EXHIBIT 64–17

Profit/Loss Diagram for a Bull Spread
Struck at Par, at Expiration, and Three Months Out

EXHIBIT 64–18

Profit/Loss Diagram for a Bear Spread Struck at Par, at Expiration, and Three Months Out

The other spread trade is a *bear spread:* It is the reverse of a bull spread. It can be created by selling a bull spread. Using put-call parity, it also can be set up by holding the underlying security, buying an in-the-money put, and selling an in-the-money call. A bear spread is equivalent to a short position in the underlying, where the position must be closed out at a price between the two strike prices. Exhibit 64–18 shows the profit/loss graph of a bear spread.

PRACTICAL PORTFOLIO STRATEGIES

The strategies discussed in the preceding section are the basic techniques used by speculators to trade options. The usual fixed income investor has a lower risk/reward profile than the speculator and specific objectives that must be accomplished; a floor on rate of return or an increase in current yield, for example. Such investors need a class of strategies different from that needed by speculators; even though the same strategies are often used, the risk is carefully controlled.

Portfolio Insurance

This is the most obvious and one of the most commonly used options strategies. An investor with a portfolio of securities who fears a decreasing market buys puts on

some or all of the portfolio; if the market falls, the puts are exercised, and the securities are sold at the strike price. Alternatively, the investor may keep the underlying security and pair off the in-the-money puts, receiving cash in compensation for the decreased value of the security. Either way, the investor has limited losses on the portfolio in exchange for selling off return in a stable or rising market.

As the strike price of the put increases, so does its cost and the resulting impact on the stable market rate of return. Often, out-of-the-money options are used; the floor on returns is lower because the strike price is lower, but the lower cost of the options means that less return is given up if the market is flat or rises. By put-call parity, such a position is equivalent to holding a call option struck at or in-the-money.

Another popular strategy is to buy at-the-money options on a portion of the portfolio. This reduces but does not eliminate downside risk: Exhibit 64–19 shows the profit/loss graphs at expiration for positions with different percentages of the portfolio hedged with an at-the-money put. Note that all the graphs intersect at a single point. This is the point where the initial cost of the option is equal to the value of the option at expiration, which is the break-even price for this trade.

It is not possible to buy options on many classes of securities that may well be held in a portfolio. Perfect insurance for such securities is unattainable, but cross-market hedging often will permit a reduction in downside risk to acceptable levels.

EXHIBIT 64–19

Hedged Underlying Security with Puts
Long Puts Struck at Par, at Expiration

Covered Calls

Writing covered calls is a strategy that sells volatility in return for fees. An investor who holds a portfolio sells calls on some or all of the portfolio in return for fees. If the market stays the same or falls, the investor pockets the option fees. If the market increases until the calls are in-the-money, the investor is called out by the option holder. In other words, possible gains on the portfolio are sold for fee income.

Often the investor wishes to preserve some upside potential. Just as in the portfolio insurance example, there are two different ways to do this. The calls can be struck out-of-the-money, that is, above the current market price. This strategy allows all gains up to the strike price to be captured. If the bonds in the portfolio are currently trading below the original purchase price, a popular strategy is to sell calls struck at this purchase price. This provides fee income and increased current yield but prevents the possibility that the bonds will be called at a price below the original purchase price and the portfolio will book a capital loss.

Otherwise, calls can be sold on a portion of the portfolio. This allows unlimited price gains to be captured on the remainder. Exhibit 64–20 shows the profit/loss graph of a covered call program where different portions of the portfolio have calls sold against them.

EXHIBIT 64–20

Covered Call Writing Program
Short Calls Struck at Par, at Expiration

Buy-Writes and Writing Puts

Buy-writes and writing puts are two very closely related strategies for selling volatility that most investors think of as entirely different. To execute a buy-write, a bond is purchased, and simultaneously, a call is written on this bond to the same dealer for the fee income. If the security is trading above the strike price at expiration, the security is called, and the investor is left with just the option fee. If the price of the security has fallen, the investor is left holding the security, but the total cost of the security is reduced by the fee from the call. By put-call parity, this trade is identical to writing a put struck at-the-money. In both cases, the investor is delivered the security only if the price of the security is lower than the price of the original sale.

In the MBS market, a buy-write is composed of forward purchases and short calls on forward delivery contracts (standard TBA transactions). If the call is exercised, it offsets the forward sale, and the buyer never takes delivery of the security, keeping the fee income. Otherwise, the buyer will receive the security on the forward settlement date for the original forward sale price, although the total price is decreased by the value of the option fee.

Put writing is a more general strategy that applies to all fixed income options markets. The investor writes a put for the fee income and receives the underlying instrument at expiration if the security trades below the strike price. This can be a very effective strategy if carefully structured. An investor may feel that a security offers real value if bought at a certain price below the market. The investor could then write puts struck at that price. If the security falls below the strike, it is delivered at a price that is more agreeable than the current price. Otherwise, the investor simply pockets the fee income.

VOLATILITY

Volatility plays a key role in the valuation of options and in option strategies. In this section we focus on methods for estimating volatility.

Statistically, volatility is a measure of the dispersion or spread of observations around the mean of the set of observations. If volatility seems strangely like a standard deviation, then you remember your statistics. When people speak of volatility, all they really are talking about is a standard deviation.

For fixed income securities, volatility is expressed in yield or price units, either on a percentage or on an absolute basis. Price volatilities can be computed for any security. Yield volatilities should be computed only for those securities with a consistent method for computing yield. Given the complexity of calculating a yield on a MBS and the variation of results, the predominant volatility measure in the MBS market is price volatility. The government bond market, where yields are easily calculated, favors yield volatility.

There are two types of volatility: empirical volatility and implied volatility. Each is described below.

Empirical Volatility

Empirical volatility is the actual, historical market volatility of a specific security. These numbers typically are calculated for various time periods (10 days, 30 days, 360 days) and usually are annualized.[1] Calculating an empirical volatility is nothing more than calculating the standard deviation of a time series. Thus an absolute volatility is the annualized standard deviation of daily price or yield changes, assuming a normal distribution.

Percentage volatility is the annualized standard deviation of the daily change in the log of prices or yields, assuming a lognormal distribution of prices or yields. Similar to the daily absolute yield changes, the logs of the daily yield changes have a slight bias toward lower yields. The intuitive approach to calculating a percentage volatility is to find the standard deviation of daily *returns,* assuming a normal distribution. This approach is equivalent to the lognormal assumption as long as the distribution can be characterized as being equally normal and log normal and, the changes in prices are taken on a small interval, such as daily.

As mentioned previously, empirical volatility can be measured over various time periods. The most common interval on which the standard deviation is taken is 30 days; other common intervals are 10 days and 360 days. The choice of interval determines how quickly and to what degree an empirical volatility responds to deviations. As the time period shortens, volatility increasingly reflects current conditions but is more unstable as each sample asserts greater influence in the deviation. Conversely, as the interval increases, more of a lag and a smoothing are introduced into the calculation.

The interval used to calculate an empirical volatility should be chosen to match the length of the option contract. This provides the investor with an indication of how volatile the underlying security has been recently and how this relates to the volatility employed to price the option.

With no industry standard for volatility units, converting between the price and yield expression of absolute or percentage volatility is a useful skill. The path to follow to convert from one unit to the next is shown in Exhibit 64–21. The modified duration of a security provides the link between price and yield volatilities. Modified duration is defined as the percentage change in price divided by the absolute change in yield.

Implied Volatility

Implied volatility is merely the market's expectation of future volatility over a specified time period. An option's price is a function of the volatility employed, so where an option's price is known, the implied volatility can be derived. Although it sounds straightforward, calculating an implied volatility is far more

1. When annualizing a volatility, certain assumptions are inherent to the calculation. To convert from daily to yearly volatility, for example, the daily volatility is multiplied by the square root of the number of business days in the year, approximately 250.

EXHIBIT 64–21

Converting Volatility Measures

complicated than calculating an empirical volatility because expectations cannot be observed directly. An option pricing model along with a mathematical method to infer the volatility must be employed. The result of this calculation is a percentage price volatility that can be converted to the various types of volatility measures discussed previously (see Exhibit 64–21).

Owing to the existence and liquidity of fixed income options, proxies for implied volatilities can be derived from Treasuries. Options on Treasury futures listed on the Chicago Board of Trade (CBOT) are often the best vehicles for implied volatility calculations. The resulting implied volatility provides a good indication of the market's expected volatility for the Treasuries with maturities similar to that of the particular bond futures contract in question. The implied volatility on the 10-year bond futures contract, for example, is a useful proxy for the market's expected volatility on intermediate-term Treasury securities.

KEY POINTS

- An option is the right but not the obligation to buy (a call option) or to sell (a put option) a security at a fixed price (strike price or exercise). The expiration date is the last date on which the option can be exercised. Some options can be exercised at any time until expiration (American options); some options can only be exercised at expiration (European options).

- The relationship among the price of a security, the price of a put, and the price of a call is called the put-call parity and is one of the foundations of the options markets.
- The price of an option is the sum of its intrinsic value and time value.
- Volatility measures the variability of the price or the yield of a security. It measures only the magnitude of the moves, not the direction. Standard option pricing models make no assumptions about the future direction of prices but only about the distribution of these prices. Volatility is the parameter used for option pricing because it measures how wide this distribution will be. The higher the volatility of a security, the higher is the price of options on that security.
- To manage an option position, quantitative ways to describe the behavior of an option are needed. These include an options delta, gamma, and theta.
- Any investor with specific goals can use option strategies to tailor the performance of a portfolio.
- Because it is impossible to obtain the effects of options by using only the underlying securities, a whole new universe of strategic possibilities is opened up. In particular, investors with contingent liabilities cannot create an adequate hedge without the use of options.
- Increased liquidity in the options markets and a better understanding of the properties of options make option strategies more accessible to the average investor and allow these strategies to be used for a wider range of securities. In particular, the over-the-counter options markets allow the purchase and sale of options with any desired strike price and expiration date.
- Refinements to option valuation technology continue to improve cross-market arbitrage trades where securities and options in one market can duplicate securities in another. As options trading removes the arbitrages, the relationships among the various markets are reinforced.

CHAPTER
SIXTY-FIVE

INTEREST-RATE CAPS AND FLOORS

GEORGE L. ALBOTA
Director
Capital Markets/Market Risk Manager
Bank of America Merrill Lynch, London

RADU S. TUNARU, PH.D.
Professor of Quantitative Finance
University of Kent, Business School

Caps and floors and their twin instrument swaptions have become the main interest rate derivatives in fixed income markets. In this chapter, we discuss these important derivatives, trying to offer some insights without delving into complex mathematical modeling. We start by first describing caps and floors, their hybrid products and their potential applications. Then we consider some simple but still robust pricing considerations based on Black's formula for caplets and floorlets, the main components of caps and floors. The importance of the forward curve volatility and skew for calibration is pointed out through examples in the last part of the chapter. The market for caps/floors is different from the swaptions market, but since both types of products are related intrinsically to the forward rates and their volatilities, they can be combined to define advanced trading strategies.

CAPS AND FLOORS DEFINED

By design, a *cap* creates a ceiling on a floating interest rate. If market rates move above the cap rate, the buyer will receive the difference between the strike rate of the cap and the underlying index rate, accrued over the corresponding period. This option can only be exercised on specific settlement dates agreed between the buyer and the seller. For instance, the bank that borrows money on a floating-rate basis can purchase a cap to protect against a rate rise above the strike. Consequently, the borrower's interest rate costs will never exceed the cap's strike rate.

A *floor* is the opposite of a cap. If market rates move below the floor rate, the buyer receives the difference between the floor's strike and the underlying rate. It is common for treasurers and asset managers to buy floors as a way of locking in a minimum rate of return on floating-rate assets. The following example illustrates this point. Anticipating that market rates will stay low for a period of time, an asset

EXHIBIT 65–1

Example of a Floor Option

Data obtained from Bloomberg Financial L.P.

manager decides to buy a floor at 1.5% against the return on a floating-rate asset linked to three-month EURIBOR. On February 11, 2009, the asset manager contacts a bank and agrees to buy a EUR 10 million notional, four-year maturity, 1.5% strike floor on three-month EURIBOR. Exhibit 65–1 shows the three-month forward curve on the trading day, the realized three-month EURIBOR rates, the actual payoff of the floor, and the potential payoff for the remaining fixing dates based on the forward curve as of February 14, 2011. On each of the floor's reset dates when three-month EURIBOR fixes below the 1.5% strike, the loss on the asset is offset by the floor's positive payoff. The actual floor on the asset's return is lower than 1.5% because of the premium paid by the asset manager to enter the floor. This cost can be regarded as a running spread over the life of the floor and subtracted from the floor's strike. If in our example the premium would have been 40 basis points (bps), then, disregarding any discounting effects from funding, the average cost per year would be 10 bps and the actual floor level would be 1.40%. (The correct approach is to divide the premium by the annuity covering the life of the floor.)

COLLARS AND CORRIDORS

A *collar* is a trading strategy created by simultaneously purchasing a cap (floor) and selling a floor (cap) with identical maturities, reference rates, and notionals but different strikes. Usually, the cap and the floor are out-of-the-money.

Because the premium paid on the cap (floor) is partially offset by the premium received on the floor (cap), the collar is a cheaper way of hedging risk. This cost reduction comes at the price of giving up the potential benefit of favorable rate movements outside the range defined by the two strikes. A borrower entering a collar is hedged against a rise in the interest rates above the cap strike but gives up any benefit when the rates move below the floor strike. In between the two strikes, the borrower continues to pay the index rate. Unlike a cap or a floor, a premium payment may or may not be necessary depending on the two strikes, volatilities and notional amounts. When the premium of the cap and that of the floor are equal, a "zero cost collar" can be structured. Outside the range defined by the two strikes, a collar is equivalent in terms of cash flows to an interest rate swap paying a fixed-rate and receiving a floating-rate.

A *corridor* is a strategy in which the cost of purchasing a cap is offset by the simultaneous sale of another cap with a higher strike. The buyer is hedged against an increase in the index rate between the two strikes, but loses this protection if the rates go above the higher strike. It is possible to offset entirely the cost of the lower strike cap by increasing the notional of the higher strike cap. However, if the index rate goes through the higher strike, the buyer will no longer be protected because of the notional mismatch between the two caps.

HYBRID TYPE INSTRUMENTS

Following the success of the caps and floors market, a wide range of hybrid type instruments have appeared, trying to tailor the risk to clients' specifications. We describe a few of the more popular ones below.

A *conditional premium cap/floor* is a contract between two parties in which the seller agrees to pay the buyer if the underlying interest rate index is above/below the fixed strike rate (cap/floor) on the specified fixing dates. The seller pays the difference in interest (i.e., between the index and the strike rates) adjusted for the relevant day count fraction. The buyer pays the seller a premium, as a percentage of the notional, only on those occasions when the option is in-the-money. Thus, if the index never fixes above/below the strike rate, the buyer will never have to pay a premium.

A *chooser cap/floor* is an interest rate cap/floor with a fixed number of possible exercises out of the total market fixing times. If the interest rate index fixes above the cap strike/below the floor strike, more times than the agreed number of exercises, then the buyer will lose the protection. This contract is cheaper than a vanilla cap/floor as its premium is related to the number of activation periods. The premium is paid upfront.

Another hybrid product is a *reset strike cap/floor,* which is just a standard cap/floor that has a secondary strike rate. If the underlying index rate is higher/lower than this secondary strike level, then the cap/floor strike is changed to the reset strike level for that period. The premium is quoted as a percentage of the initial notional and it can be paid up front or pay-as-you-go.

POTENTIAL APPLICATIONS OF CAPS AND FLOORS

Here are a few examples of the potential use of caps and floors:

- *Hedging of options embedded in assets/liabilities:* It is common for insurance companies and pension funds to use caps/floors to hedge the risk arising from guaranteed-payoff annuity products.
- *Hedging floating-rate assets/liabilities:* Debt managers can buy floors to protect against potential losses on outstanding fixed-rate debt when rates fall (fixed coupon debt can also be swapped into floating-rate debt and a cap can be added to fix the maximum rate).
- *Create synthetic positions:* Using caps and floors alone or in combination with other derivatives, investors can achieve a wide variety of payoff profiles.
- *Enhance returns:* Hedge funds frequently use caps/floors to express views on the level of interest rates at different points in time. By purchasing options, they have a limited downside (the paid premium), but a virtually unlimited upside if their views prove correct. In general, these positions are not hedged. If these strategies are profitable, hedge funds can put hedges in place to lock in their profits or they can unwind the positions before expiry. Sometimes, these funds sell caps and floors to enhance the return on investments.

CAPLETS AND FLOORLETS

When purchasing a cap or a floor, the buyer is actually entering a collection of sequentially maturing European style options with the same strike called, respectively, *caplets* or *floorlets*. A caplet/floorlet payoff is positive if the underlying rate is higher/lower than the strike, essentially allowing the buyer to receive the underlying rate floored at the strike or pay the underlying rate capped at the strike.

A typical caplet/floorlet uses the reference rate, for instance three-month LIBOR/EURIBOR. Usually, the rate (L) is observed at the beginning of the caplet/floorlet calculation period on the reset date (D_R), which, for the major currencies, is two business days before the actual start date of the caplet/floorlet (D_S). At expiry (D_E) the rate is compared with the strike rate (K) and the payoff is accrued for the duration of the calculation period (from D_S to D_E). The payoff of a caplet on the payment date can be written as:

$$\max\left[L_R(tenor) - K, 0\right] cvg(D_S, D_E)$$

where $cvg(D_S, D_E)$ is the accrual period expressed as a year fraction calculated using the day count convention dictated by the respective currency (usually Actual/360; number of days during the period from time D_S to D_E normalized by the number of days in a year).

EXHIBIT 65–2

Black's Pricing Formulae for the Normal Model and Log-normal Model

Model	Caplet Price	Floorlet Price
Normal	$\sigma_{bp}\sqrt{t_R}[n(d)+dN(d)]cvg(D_S, D_E)df(0, t_E)$	$\sigma_{bp}\sqrt{t_R}[n(d)-dN(-d)]cvg(D_S, D_E)df(0, t_E)$
LN	$[FN(d_1)-KN(d_2)]cvg(D_S, D_E)df(0, t_E)$	$[-FN(-d_1)+KN(-d_2)]cvg(D_S, D_E)df(0, t_E)$
	$d=\dfrac{F-K}{\sigma_{bp}\sqrt{t_R}}$	$d_{1,2}=\dfrac{\ln\left(\dfrac{F}{K}\right)}{\sigma_{LN}\sqrt{t_R}}\pm\dfrac{1}{2}\sigma_{LN}\sqrt{t_R}$
	$N(d)=\int_{-\infty}^{d}\dfrac{1}{\sqrt{2\pi}}e^{-\frac{1}{2}x^2}dx$	$n(d)=\dfrac{1}{\sqrt{2\pi}}e^{-\frac{1}{2}d^2}$
Forward rate	$F=F(0, t_S, t_E)=\left[\dfrac{df(0, t_S)}{df(0, t_E)}-1\right]\dfrac{1}{cvg(t_S, t_E)}$	

t_R and t_E represent the time (in years) from the valuation date.
$F(t, t_S, t_E)$ - forward rate spanning the period from t_S to t_E observed at time t (t = 0 is the current time).
$df(t, t_S)$ - discount factor from time t to time t_S.

The market convention is to use the Black formula (the log-normal model or sometimes the normal model) to price caplets/floorlets.[1] Exhibit 65–2 summarizes the pricing formulae for each of the two versions of the model:

We present a numerical example based on the log-normal model for the calculation of the price of a caplet-floorlet straddle. The details of the option are presented below for a valuation date of February 14, 2011, that is equivalent to $t_R = 4.99421$:

Start Date	End Date	Fixing Date	cvg	Forward	Strike	DFs	Vol	Price (bps)
16/02/16	16/08/16	12/02/16	0.50556	3.94234%	4.234%	0.84913	23.29%	72.73

$$d_{1,2}=\frac{\ln\left(\dfrac{3.94234\%}{4.234\%}\right)}{23.29\%\sqrt{4.99421}}\pm\frac{1}{2}23.29\%\sqrt{4.99421}$$

$$\text{Caplet}=(3.94234\%N(0.1230)-4.234\%N(-0.3975))\times 0.50556\times 0.84913=0.3010\%$$

$$\text{Floorlet}=(-3.94234\%N(-0.1230)+4.234\%N(0.3975))\times 0.50556\times 0.84913=0.4263\%$$

Because caplets/floorlets are essentially calls/puts on interest rates, put-call parity holds. A long position in a caplet combined with a short position in a floorlet is equivalent to a position in a forward rate agreement (FRA):

$$\text{Caplet}-\text{Floorlet}=(F-K)\,cvg\,(t_S, t_E)\,df\,(0, t_E)=FRA$$

Hence, for pricing purposes, only the caplet or the floorlet needs to be priced.

1. Fischer Black, "The Pricing of Commodity Contracts," *Journal of Financial Economics*, 3 (1976), pp. 167–179.

The validity of Black's model has been discussed in Hull.[2] If interest rates over the contract's life are assumed to be either constant or deterministic, the forward price equals the futures price, making Black's log-normal model appropriate. Furthermore, Black's model holds when interest rates are stochastic, provided that the discounting is done at today's maturity t_E zero-rate, given by $df(0, t_E)$. To summarize, Black's model for interest rates exhibits the same shortcomings as the Black-Scholes model for equities, namely that it assumes constant volatility.

INSIGHTS ON TRADING CAPS AND FLOORS

Caps/floors trade in the market either *spot starting* (i.e., as an A-year maturity trade), or *forward starting,* in which case the market convention is to name the trade as an A × B cap/floor, meaning the contract kicks-in after A-years and matures in B-years' time from the spot time. When the underlying rate is a LIBOR rate, the number of caplets and floorlets is usually determined by the tenor of the rate; that is, if the tenor is three months, the trade will have four caplet/floorlets per year.

The distinction in quotation is very important for the calibration of models using market data. The array of prices with various maturities imply a volatility surface and various models are judged in terms of performance depending on how well they can fit this surface without introducing arbitrage.

Exhibit 65–3 shows the prices of some at-the-money (ATM) forward starting cap/floor straddles for EUR, GBP, and USD (as of February 14, 2011) that could have been seen on different broker screens in financial markets.

The most common reference *rates* for these contracts are LIBOR or equivalent rates for the most liquid currencies: EUR, USD, GBP, and JPY. However, there is a large market for caps and floors on constant maturity swaps (CMS) rates and CMS spreads. These latter instruments can trade as *single look options* (one caplet/floorlet resetting and paying in arrears) or as regular spot or forward starting with quarterly or semiannual coupons. The difference with the CMS cap/floor contract is that the interest rate index is a swap rate, the forward rates are calculated from the forward swap rates plus a convexity adjustment. The premium is quoted as a percentage of the initial notional amount and it is generally paid either up front or pay-as-you-go, being spread over the life of the contract.

Since caps (floors) are collections of caplets/floorlets, the ATM strike rate is chosen such that all the caplets/floorlets are close to ATM. The convention is to define it as a weighted average of the ATM strikes (forward rates) of the individual caplets/floorlets. The weights are the discount factors corresponding to the expiry of each caplet/floorlet. The ATM strike satisfies the following equality ('*cvg*' here denotes the difference between the two times):

$$\sum_{i=\text{start}}^{\text{end}-1} F(0, t_i, t_{i+1}) cvg(t_i, t_{i+1}) df(0, t_{i+1}) = \sum_{i=\text{start}}^{\text{end}-1} K_{ATM} cvg(t_i, t_{i+1}) df(0, t_{i+1})$$

5×7	295	383	335
5×10	732	937	788
10×15	669	794	634
10×20	1,276	1,408	1,171

Data obtained from Bloomberg Finance L.P.

where $t_{\text{start/end}}$ are the start/end dates of the cap/floor. If the strike of a cap is higher than the ATM strike then the cap is said to be in-the-money, otherwise the cap is out-of-the-money (OTM). The converse holds for a floor.

Because the ATM strike is calculated as a weighted average of the forward rates, in an environment with steep forward curves, some of the caplets will be deep in-the-money and hence they will be very expensive. In these instances, one solution to get a similar hedging performance at a reduced cost is to use a *step-up cap*. This product is a variation of the standard cap which uses progressively higher strikes (instead of a single fixed strike for all the caplets) to account for the higher forward rates along the forward curve. A similar product is a flexible cap/floor where the range of strikes is pre-agreed at given levels, not necessarily increasing or decreasing.

Using the put-call parity relationship for caplets/floorlets, we can easily verify that a long position in a cap combined with a short position in a floor with the same features is equivalent with paying fixed in a spot, or forward

starting swap, where the two legs have the same reset frequency and day counting convention.

The convention for reset and payment for caps and floors is reset in advance and payment in arrears. That is, the payoff rate is observed at the beginning of the caplet/floorlet period and payment occurs at the end of each caplet/floorlet period. Because of this feature, spot starting contracts do not have the first caplet/floorlet, since the reset of the payoff rate would happen on the trading date and hence the payoff would be known exactly. For instance, a spot starting two-year cap with quarterly observations will only have seven caplets. Other variations like reset in arrears and payment in arrears are also quoted and traded in the marketplace.

Furthermore, the usual characteristics of options apply to caps and floors. The buyer pays the premium, which is a function of the strike rate, the period covered, and the volatility of the underlying rates. The cost of a cap/floor is the sum of the premiums of each individual component caplet/floorlet. A bank's/dealer's book is made of a large number of caps/floors with different start and maturity dates. Each of these trades is priced using a different volatility depending on the specific features of the product. To this end, banks/dealers construct caplet/floorlet volatility curves. For the same underlying rate, these curves show the caplet/floorlet volatility for different expiry dates. These volatilities are bootstrapped from the prices of the quoted caps/floors (ATM cap/floor straddles; a straddle is a simultaneous position in a cap and a floor with the same notional, strike, maturity, and underlying rate). Information about the volatility of the rates can be also inferred from the prices of options on short rate futures (for instance EURIBOR or EURO-dollar futures). In general, the liquidity of these futures contracts is concentrated in the short expiries. As a result, many traders' bootstrapping procedures use both types of instruments as inputs (i.e., options on futures for short expiries and forward starting caps/floors for longer expiries). Missing points are inferred based on different interpolation schemes, which are beyond the scope of this chapter. An example of the EUR cap/floor volatility curve is illustrated in Exhibit 65–4.

The market convention is to quote cap/floor prices in terms of the implied volatility which sets the Black's model price equal to the market premium. This is a matter of convenience, as implied volatilities are more stable over time than premiums, but it should not be interpreted to mean that market participants view the Black model as being a correct depiction of reality.

Broker screens show prices (quoted as implied volatilities) for both ATM and OTM caps/floors for different tenors. A snapshot of the EUR cap/floor market smile/skew for different maturities is depicted in Exhibit 65–5. Depending on the currency, the conventions for the underlying index rate can differ. For instance, the EUR cap/floor market uses three-month EURIBOR for maturities of up to two years and six-month EURIBOR for higher tenors.

The presence of volatility smiles/skews is a clear indication that Black's model is just a pricing convention rather than rigorously inferred valuation. When it comes to modeling the volatility smile, the market standard (for both caps/floors and swaptions) is the stochastic alpha, beta, and rho (SABR) model

EXHIBIT 65–4

Example of EUR Cap/Floor Implied Volatility as a Function of Maturity Date

Note: Implied volatility obtained from the Black Model.

Data obtained from Bloomberg Finance L.P.

EXHIBIT 65–5

Example of EUR Cap/Floor Volatilities as a Function of Strike Rate

Data obtained from Bloomberg Finance L.P.

developed by Hagan and his associates.[3] For caps/floors there is an added level of complexity because one needs to model the smiles for the underlying caplets/floorlets.

The convention in the market is to refer to each caplet indicating when it will start and when it will end. For example a 6M×9M caplet will kick in after 6M and will mature in 9M. In an idealized world in which caps/floors are available for sequential maturities (i.e., every three months in the case of USD), one possible approach to calibrating the caplet/floorlet smiles could be the following. Start with the 3M×6M caplet for which prices for different strikes are available and calibrate the SABR model. Select one particular strike, say K, and move to the nine-month cap/floor struck at K. Using the price for the 3M×6M caplet/floorlet struck at K (from the previous step) determine the price of a 6M×9M caplet/floorlet struck at K and its implied volatility. By repeating this procedure for all the available strikes/prices for the nine-month cap/floor one can build the smile/skew for the 6M×9M caplet/floorlet and calibrate the SABR model to it. The process continues until all the caplets/floorlets up to a certain tenor (usually 30 year, giving 119 caplets/floorlets) have been calibrated. Exhibit 65–6 illustrates this procedure.

In reality the calibration procedure is more difficult. One issue is the difference in underlying index rates for different tenors (e.g., for EUR caps/floors reference three-month EURIBOR up to two-year and six-month EURIBOR thereafter). Another is the fact that the maturity grid is coarser, which makes interpolation necessary for working out intermediate caplets/floorlets volatilities. Some remedies are possible and banks/dealers use different methods to overcome these problems.

EXHIBIT 65–6

Caplet/Floorlet Smile/Skew Calibration

Tenor (Cap/Floor)	Caplet/Floorlet Calibration				
6 months	3M×6M				
9 months	3M×6M	6M×9M			
1 year	3M×6M	6M×9M	9M×12M		
15 months	3M×6M	6M×9M	9M×12M	12M×15M	
18 months	3M×6M	6M×9M	9M×12M	12M×15M	15M×18M
...					

3. See Patrick S. Hagan, "Convexity Conundrums: Pricing CMS Swaps, Caps and Floors," *Wilmott Magazine* (March 2003), pp. 38–44; Patrick S. Hagan, Deep Kumar, Andrew S. Lesniewski, and Diana E. Woodwar, "Managing Smile Risk," *Wilmott Magazine* (Autumn 2002), pp. 84–108, and; Patrick S. Hagan, Andrew S. Lesniewski, and Diana E. and Woodward, "Probability Distribution in the SABR Model of Stochastic Volatility," Working Paper, 2004.

Information about the three-month forward rates smiles/skews can be retrieved from options on short rate futures (EURO-dollar or EURIBOR futures). In the past, when the basis three-month to six-month was small and less volatile, one approach was to use the relationship between two successive three-month EURIBOR rates and a six-month EURIBOR (compounding) and the autocorrelation for the three-month EURIBORs. This could then be used to derive rules that linked three-month with six-month volatility. Once the SABR parameters for each caplet/floorlet are available, any cap/floor can be priced using the normal/log-normal volatilities implied by the SABR model for a particular strike. Exhibit 65–7 provides an example of a cap/floor straddle pricing for EUR 5×10 ATM cap/floor straddle (CFS) priced as of February 14, 2011. The quotation means that the straddle will start in five years and will end in 10 years' time.

CAPS AND FLOORS VERSUS SWAPTIONS WEDGE

A *swaption* is a European option that allows the buyer to enter a swap upon exercise. The convention is to describe a swaption as an A-year into B-year trade; that is, upon the option expiring at A the parties will enter into a swap lasting B more years. Swaptions are divided into two types: payer and receiver swaptions, namely, the buyer of a swaption enters a B-years swap upon exercise (in A-years' time) where he will pay/receive the fixed side at a level equal to the strike of the swaption.

Since swaps can be defined as portfolios of forward rates weighted by the discount factors, swaptions can be regarded as options on portfolios of forward rates.

$$SR = \sum_{i=1}^{nr.flt\ coupons-1} \frac{cvg(t_i, t_{i+1})df(0, t_{i+1})}{\sum_{j=1}^{nr.fxd\ coupons-1} cvg(t_j, t_{j+1})df(0, t_{j+1})} F(0, t_i, t_{i+1})$$

where SR denotes the par swap rate and all the notation is as before.

In the beginning of this chapter we stated that caps/floors and swaptions are the building blocks of the interest rates derivatives market. On the other hand, we saw that caps/floors are portfolios of options on individual forward rates, whereas swaptions are options on portfolios of forward rates. The question which naturally arises is whether there is a relationship between the prices of caps/floors on one side and swaptions on the other side. A long/short position in a cap/floor combined with a short/long position in a swaption, both sharing the same set of spanning forward rates, is called a *wedge*. Some of the most common wedges are 2×4 cap/floor straddle (CFS) versus 2Y2Y P/R/S payer/receiver straddle (P/R/S) and 5×10 versus 5Y5Y.

If we assume that the caplets/floorlets determine the volatility of the forward rates, then it becomes clear that the driving force behind the price difference between caps/floors and swaptions is the correlation between the forward rates. In addition, the payoff functions of the two instruments impose constraints on the

18-Feb-19	16-Aug-19	16-Aug-19	14-Feb-19	0.49722	4.347%	4.234%	0.74813	20.020%	71.23
16-Aug-19	17-Feb-20	17-Feb-20	14-Aug-19	0.51389	4.419%	4.234%	0.73151	20.020%	74.86
17-Feb-20	17-Aug-20	17-Aug-20	13-Feb-20	0.50556	4.385%	4.234%	0.71565	19.150%	70.62
17-Aug-20	16-Feb-21	16-Feb-21	13-Aug-20	0.50833	4.439%	4.234%	0.69986	19.150%	71.82
								Total	735.247

relationship between their premiums. Because of the convexity of the payoff we have the following inequality (here we made the assumption that the underlying swap of the swaption has the same day count convention and payment frequency on the two legs):

$$\sum_{i=1}^{nr.forward\ rates} df(t_1, t_{i+1}) \max(F(t, t_i, t_{i+1}) - K, 0)\, cvg(t_i, t_{i+1})$$
$$\geq \max\left(\sum_{i=1}^{nr.forward\ rates} df(t, t_{i+1})(F(t, t_i, t_{i+1}) - K, 0)\, cvg(t_i, t_{i+1}), 0\right)$$

The above inequality implies that the value of a payer swaption will always be less than the value of a cap (both defined on the same set of forward rates).

In reality, the two products behave rather independently of each other and the implied correlation between the forward rates can at times exceed normal limits or what can be deemed as cheap/expensive given the market stance. Some market participants, banks and hedge funds, have tried to exploit these discrepancies and put on arbitrage plays on the correlation level. In general, these strategies require a long holding period and hence exposure to the mark to market fluctuations. On several occasions in financial markets the unwinding of such positions (which did not performed as expected) caused severe dislocations in the wedge.

The relatively high volatility of the wedge can be explained by the fact that the two products belong to two different markets with different supply/demand dynamics. In the cap/floor market, banks are natural suppliers of cap/floor volatility from their issuance of exotic structures such as snowballs, capped/floored floating-rate notes (FRNs), range accruals, callable trades, and the like. In contrast, banks may decide to buy caps perhaps as a "cheaper" alternative protection against inflation and floors for general asset/liability management. The swaptions market is usually accessed by more sophisticated investors such as banks, pension funds, and hedge funds.

The spread between caps/floors and swaptions volatilities is mean-reverting. As such, one can take directional views on wedges. The interplay between the future shape of the yield-curve (bull/bear steepening, or flattening) and volatility is a major factor affecting the dynamics of the wedge. The "carry and roll" are very important issues when one decides to enact such a trade. Another important aspect is the fact that caps/floors will have on "average" more gamma[4] than a swaption (both trades sharing the same driving forward rates).

We mentioned earlier that the future shape of the curve and the volatility are important factors in the behavior of the wedge. Based on the historical analysis of yield curves, one can expect to see certain behavior of the correlation between the forward rates and volatility under different curve scenarios. From an

4. The gamma is the sensitivity of changes in the value of the caps/floors with respect to large changes in the interest yield. It is measured by the second derivative of the caps/floors price with respect to yield.

EXHIBIT 65–8

Example of EUR 2×4 CFS versus 2y2y Swaption Straddle Wedge against the 5y-2y Swap Spread

Data obtained from Bloomberg Finance L.P.

intuitive point of view, a decrease in correlation would imply more independence in the move of the forward rates and hence, potentially higher values for the caps/floors. On the other hand, since a swap is a portfolio of forward rates with positive weights, one would expect to see a lower volatility and hence a lower value for a swaption. Under such a scenario, a cap/floor would be more valuable on a relative basis. Several studies on the shape of the yield curves have documented a decrease in correlation in steepening environments in which the forward rate curve becomes progressively steeper and the forwards more de-correlated. Based on such observations, market participants can take positions on the wedge. Exhibit 65–8 shows the evolution of the EUR 2×4 CFS versus 2y-2y swaption straddle wedge against the curve of slope (5y-2y). The exhibit seems to reinforce the observation that the steepening causes the correlation between the forward rates to drop and makes the wedge a better hold.

KEY POINTS

- Caps and floors are portfolio of European options and they offer a suitable solution for hedging interest rate risk across time.
- Hybrid type caps and floors include conditional premium cap/floor, chooser cap/floor, and reset strike cap/floor.
- Pricing is done for each individual caplet or floorlet and there is a put-call parity relationship.

- Cheaper hedging solutions can be obtained by giving up some upside opportunity and creating trading strategies such as corridor and collar. Swaptions are another viable alternative for hedging interest rate risk but in general the swaptions market is different from the caps/floors market.
- Black's model is used for price quotation by convenience. The SABR model is used by most banks for calibration of implied volatilities with various maturities.
- Advanced trading strategies such as wedges can be implemented to take advantage of understanding how volatility affects the forward rates.

CHAPTER
SIXTY-SIX

CREDIT DERIVATIVES

DOMINIC O'KANE, D.PHIL. (OXON)
Affiliated Professor of Finance
EDHEC Business School

Since the turn of the century, the credit derivatives market has become the main destination for those wishing to hedge credit risk and those looking for credit-based investments not available in the traditional cash credit markets. Two products dominate. The first is the single-name credit default swap (CDS), which transfers the default risk of a specific corporate or sovereign. The second is the CDS index, essentially a portfolio of CDS packaged into a single transaction. Together they constitute over 90% of all credit derivative transactions.

The purpose of this chapter is to set out a comprehensive description of the CDS contract, and specifically the detailed mechanics of how it works. We follow this with a detailed description of the mechanics of the CDS indices. We defer a detailed discussion of the pricing and risk-management of CDS and CDS indices to Chapter 67. However, we begin with a history of the evolution of the credit derivatives market.

EVOLUTION OF THE CREDIT DERIVATIVES MARKET

The credit derivatives market began in the early 1990s as a branch of structured finance that involved creating highly bespoke transactions customized to a particular requirement. These included hedging a credit risk, creating a structured investment product, or managing the regulatory capital of both sovereign and corporate credit risk.

By the mid 1990s the concept of a CDS contract had been established. However, the market lacked standardized legal definitions for the credit events that trigger the contract, and for the protected debt obligations. This meant that pretrade negotiations between parties often required legal assistance in order to ensure that the triggering events and the hedged debt obligations were clearly defined and understood. In addition to increasing transaction costs, this meant that trades could take several days to approve and settle.

The significant growth phase of the CDS market therefore only started following the publication of the first *Credit Derivative Definitions* by the International

The author acknowledges the helpful comments of Samuel Morgan and Mark Ames.

Swaps and Dealers Association (ISDA) in 1999. This document, which became known as ISDA '99, was a response to the legal disputes that arose following the Asian crisis of 1997 and the Russian default of 1998. In addition to the new definitions, ISDA '99 also created a short-form confirmation document that required parties to simply tick a box in order to specify the characteristics of their trade. This made it possible for the market to develop a standard contract, i.e., a contract that has a certain number of characteristics that a majority of buyers and sellers can agree on and which therefore attracts the greatest liquidity. Following its adoption of ISDA '99, the CDS market began a period of very rapid expansion, growing from a total outstanding notional of $632 billion in 2001 to $62 trillion by the end of 2007.[1]

A number of important changes were made to the credit derivatives market between 2000 and 2003. Many of these changes were in response to some of the credit events that had occurred[2] after the end of the dot.com boom and the events of September 11, 2001, and addressed such issues as reference entity specification, guarantees, debt restructuring, deliverability, and successors. Of these, perhaps the most problematic, since it led to a regional split in the market standard, was in relation to the treatment of restructuring as a credit event. This is discussed in detail later.

The period from 2004 to 2007 saw the arrival of the CDS indices. These were adopted very rapidly by the market and became highly traded and highly liquid. They were particularly favored by credit investors who viewed them as a simple and cheap way to take a macro-level exposure to the credit markets, in much the same way as equity index futures permit investors to take a macro-level exposure to the equity markets.

In late 2003, the credit derivatives market established an automatic trade confirmation system at the Depository Trust and Clearing Corporation (DTCC) in New York, the aim being to speed up the confirmation of trades and to remove the backlog of unsigned confirmations that had built up. Then in late 2007, the DTCC also established itself as the keeper of the comprehensive trade database—the official legal record for all confirmed trades. It also set an infrastructure to automate and standardize post-trade processing.

The period 2008–2010 saw a considerable upheaval in the CDS market as regulators responded to the aftermath of the Lehman bankruptcy and the financial crisis. Despite the fact that there were $72 billion of CDS linked to Lehman Brothers registered at the DTCC at the time of its bankruptcy, settlement of the credit event went smoothly as it used a market-wide auction procedure.[3] Nevertheless, this event caused regulators to become very concerned about

1. These numbers come from the ISDA which conducts a semiannual survey of its members who are distributed around the world.
2. These included Argentina, Armstrong, Conseco, Enron, Marconi, National Power, Railtrack, Worldcom, and Xerox.
3. The Trade Information Warehouse at the DTCC, which handled the bulk of the triggered Lehman referenced CDS contracts, reported no failures to perform.

systemic risk in the financial sector caused by the large number of outstanding contracts and a lack of transparency with respect to where the actual credit risk was sitting.[4]

In an attempt to reduce counterparty risk, regulators decided to require standard credit derivatives trades to be assigned to a centralized counterparty (CCP). To prepare the ground for these changes, the market introduced some new legal protocols. The first protocol, known as "Big Bang," was introduced in April 2009 and made the following changes:

1. Creation of a market-wide determinations committee (DC) charged with determining whether or not a credit event has occurred.
2. An automatic market-wide auction mechanism for the settlement of triggered CDS contracts following all credit events with the exception of restructuring.
3. Moving the date on which the CDS credit event protection[5] begins to the date 60 days before the date on which the request to consider whether a credit event has occurred is made to the determinations committee. This change was made in order to ensure that all existing contracts are triggered by a credit event even if the contract was initiated after the credit event occurred, but before the credit event had been determined.

At the same time, there was also a recouponing process in which the market switched to trading all CDS contracts on each credit with the same coupon irrespective of when the trade was done. This differed from the previous convention in which the coupon on a CDS was set at trade initiation in order to ensure that the contract had zero initial value. The market has also changed so that standard contracts now trade with a full first coupon, i.e., the first coupon starts accruing on the previous coupon payment date even if it is traded mid-period. Both changes have been made in order to increase the fungibility of contracts and to facilitate contract netting as a precursor to the centralized clearing of CDS contracts.

In late 2009, a second protocol known as "Small Bang" was adopted. This extended the "Big Bang" protocol to deal with the restructuring event as a trigger for the CDS. This protocol was intended for the European CDS market since restructuring is not a standard credit event in the North American CDS market

At the start of 2010, the DTCC formally linked itself to the Federal Reserve System where it is expected to fall under a global oversight framework involving U.S. and international regulators. The initiative to move credit derivative trades

4. It is worth noting that of the more than 900,000 OTC derivative contracts on Lehman's trading books, only one has been challenged due to an open confirmation. See *Report of the Financial Crisis Inquiry Commission* at http://www.fcic.gov/report.
5. For a succession event, the legal protection begins 90 days before the request.

onto CCPs was well underway, especially for CDS indices, with over fifteen trillion dollars of index trades already cleared by ICE in North America and Europe by early 2011. The first CDS to be cleared via a CCP and in compliance with the new Dodd-Frank regulations was traded in February 2011. Although most CCPs are based at exchanges, trading in the CDS market trades continue to be executed in the OTC market. The CCP then steps into the trade, placing itself between the two initial parties.

As of 2011, the size of the CDS market and CDS index markets is roughly half what it was at the market peak in 2007. A significant part of this decline can be attributed to the numerous compression cycles (discussed below) that have been carried out in the last two years. Some of it may also be due to the decrease in CDS-based and CDS index–based hedging activities of more exotic credit derivatives, in particular synthetic CDOs. Indeed a snapshot of the credit derivatives market in early 2011 shows that CDS made up 57% of the gross notional of credit derivatives, whereas CDS indices made up 34%, leaving just 9% to other transaction types.[6]

Market Participants

Since its inception, the credit derivatives market has been dominated by commercial and investment banks. Commercial banks have used CDS to hedge the credit risk of their loan book. The advantage of CDS is that they permit the bank to hedge the risk of a specific loan privately and bilaterally. This is often preferred to selling the loan because the sale of a loan by a bank usually requires the bank to notify the borrower and such a sale may be considered to be a negative signal by the borrower and as such may be damaging to the bank–borrower relationship. Surveys of the credit derivatives market have generally found that commercial banks buy more protection than they sell as their loan book hedging requires them to be net protection buyers. Their reason for selling protection is to earn income and diversify their portfolio credit exposure.

Investment banks and the dealer arms of commercial banks play an important role in the credit derivatives markets where they act as dealers. Overall they tend to run balanced books with equal amounts of protection bought and sold.

Insurance companies are also an important user of credit derivatives, primarily as a form of investment on the asset side of their business where they tend to be net sellers of protection. Hedge funds are an important market participant as they are able to play the credit markets from a long or short position and they also tend to buy roughly as much protection as they sell. They are particularly attracted by the ability to go short and the ability to leverage as the upfront payment needed to enter a CDS contract is typically much smaller than the contract notional.

Other users of the market with a lower market share include pension funds, mutual funds and companies. Funds may be more interested in CDS indices in

6. These numbers are based on a snapshot of market positions on February 11, 2011 taken from the DTCC Trade Information Warehouse Reports.

particular, as they provide a quick way to establish a diversified macro credit exposure onto which they can then add specific credit exposures.

The use of credit derivatives by companies is generally quite bespoke as it may be connected with a need to hedge or assume a very specific credit exposure that they may not wish to sell or cannot find in the bond market. For example, a company may use a CDS to hedge the credit risk of future receivables from a specific company.

Uses of Credit Derivatives

The considerable growth in the size of the CDS and CDS index market has been driven by its various uses. These are as follows:

- *Transferring credit risk:* CDS are first and foremost a tool used to transfer credit risk from one party to another. For example, banks can use CDS to transfer loan credit risk off their balance sheets into the capital markets where this risk may be assumed by an investor. This creates new loan capacity on their balance sheet.
- *Hedge credit risk:* Before the advent of CDS, it was difficult to hedge an existing credit risk by shorting corporate bonds. Buying protection using a CDS is a much easier way to achieve the same objective. CDS indices can also be used as a hedge against changes in the market-wide pricing of credit risk and also the default of individual reference entities.
- *Customization:* As the CDS market is a bilateral OTC market, parties can structure the features of a CDS in almost any way they wish. Features that can be varied include the currency, maturity, and seniority. The more the customization deviates from the market standard, the greater the associated cost and the lower the subsequent liquidity.
- *Ease*: A CDS index makes it simpler for an investment manager to assume an exposure to a diversified portfolio of credits in one transaction. The tight bid/offer spread also makes the cost of unwinding the position cheaper than the cash equivalent.
- *Leverage and yield enhancement:* A CDS and a CDS index typically require only a small upfront payment. This makes it easier to leverage the underlying risk and return compared to a fully funded cash bond.
- *Pure credit play:* The CDS and CDS index are almost a pure credit play since unlike fixed-rate corporate bonds, they have very little interest-rate sensitivity. This isolation of the credit risk is attractive for credit fund managers.
- *Risk decomposition:* CDS can be used to hedge out specific risks in securities with multiple risks. For example, they can be used to hedge

out the credit risk of convertible bonds in an attempt to isolate the economics of the embedded equity option.

- *Speculation:* CDS enable market participants to express a positive or negative view on an underlying credit while a CDS index makes it possible to go long or short macro-level credit.
- *Structured credit investments:* CDS can be used as the building blocks for more exotic structured credit investments that are created to provide a more tailored risk-return profile to specific types of investor.
- *Manage regulatory capital:* Banks can use CDS to hedge credits that have a high regulatory capital charge, provided such a hedge is recognized as being economically effective by regulators.

THE CREDIT DEFAULT SWAP

The simplest way to think of the CDS is as an insurance contract in which one party, the "protection buyer," pays a premium to be protected against a credit loss on a specific face amount of bonds or loans issued by a specified corporate or sovereign reference entity. The other party, known as the "seller of protection," receives the premium and takes on the credit risk. Since there is a buyer and a seller of the credit risk, a CDS contract does not create credit risk, it simple transfers it from the protection buyer to the protection seller as shown in Exhibit 66–1. However, unlike an insurance contract, a CDS is a traded contract that can be valued at any time. The protection seller is any investor who takes a view that the premium is attractive given his or her view of the risk of default of the reference entity.

Care needs to be taken when trading CDS to be clear about to which side of the contract we are referring. In the market, "buying" a CDS contract is usually associated with buying protection. However, buying protection is economically equivalent to shorting credit risk or selling a corporate bond issued by the reference entity. Equally, "selling" a CDS contract is economically equivalent to assuming credit risk and so is akin to buying a corporate bond issued by the

EXHIBIT 66–1

A CDS is a Bilateral Contract between a Protection Buyer and a Protection Seller

reference entity. Indeed we will demonstrate this equivalence in Chapter 67. To avoid misunderstandings, the term *buying a CDS* should always be qualified with the word *protection;* that is, *buying CDS protection*. Equally *selling a CDS* should be qualified as *selling CDS protection*. Note that this differs from the CDS index market, in which the "buyer" is usually an investor who is selling protection on the underlying portfolio of CDS. This is another reason why clarity is essential in order to prevent confusion.

CDS MECHANICS

As just stated, the purpose of the contract is to transfer the *credit event* risk of a specified face value amount of debt obligations issued by a stated *reference entity* (a corporate or sovereign) from the protection buyer to the protection seller.

The debt obligations covered by the contract are known as the *deliverable obligations* and these are usually bonds and loans of a specified seniority. This seniority is defined by specifying a *reference obligation* of the issuer with respect to which the deliverable obligations should be senior or *pari passu*. If a credit event occurs, then the protection buyer will receive a payment which is economically equal to the difference between the price of the impaired deliverable obligations and par.

The reason for protecting a basket of deliverable obligations rather than a specific obligation is that it enhances the liquidity of the market because the same contract can be used by hedgers to protect themselves against any one of many obligations of the issuer. If the market were to trade CDS on each specific debt obligation of the issuer, then liquidity and fungibility would be reduced and the cost of protection would almost certainly increase. However, there is a negative side effect because the protection buyer has the right to choose which bond is protected by the contract. He is therefore long a *delivery option*. The effect of this and how it is treated is discussed below in the section on restructuring-type credit events.

To enter into a CDS, a party trades via a dealer. This is done via the telephone or an electronic trading system. At initiation, the party usually makes an upfront payment that (depending on various factors discussed below) can be positive or negative, i.e., the payment could be from the protection seller to the protection buyer or vice versa. The model used to determine the upfront value is set out in detail in Chapter 67.

Credit protection starts on the *effective date*. Prior to the 2009 "Big Bang" protocols, this was the calendar date immediately following the trade date. However, under the new protocols, protection now begins 60 days before any request to consider whether a credit event occurred is made to the determinations committee. This change was made to ensure that all existing contracts would cancel out irrespective of whether they were traded yesterday or last year. This can create a rather strange scenario in which a protection buyer can buy protection *after the credit event* and be paid out. However, this is not as anachronistic as it may seem since the protection would have to be purchased before the credit event

was determined. Also, if the information that a likely credit event had occurred was already public at the time of the purchase then the cost of the protection would have been high and close to its post-credit event determination value.

Credit protection lasts until the scheduled termination date, more commonly known as the CDS maturity date. This will fall on one of the following dates: March 20, June 20, September 20, or December 20 of a specified year. These dates are not adjusted for holidays if they fall on a weekend. They are known as the *CDS Dates*. What this means is that at any moment in time, the scheduled termination date of the most liquid T-year CDS contract will be on the first CDS Date which falls after the date exactly T years in the future. So, for example, on April 3, 2011, the standard five-year CDS contract has a scheduled termination date of June 20, 2016. The most liquid contracts have terms of one, three, five, seven, and ten years, with greatest liquidity focused on the five-year contract.

The Premium Leg

To pay for the credit protection, the protection buyer pays the protection seller a combination of an upfront payment (which may be negative) plus a regular fixed coupon. These payments are known as the *premium leg* of the CDS. Here we will discuss the fixed coupon, deferring the discussion of the upfront payment to the end of this section.

The fixed coupon is specified at contract initiation and determines the size of the quarterly regular payments from the protection buyer to the protection seller. The size of each actual cash payment is calculated by multiplying the fixed coupon by the contract notional. This is then multiplied by the year fraction between the current and previous coupon date calculated according to an actual 360 day count convention.

Before 2009, the size of this coupon depended not just on the reference entity but also on when the CDS trade was initiated. This was because the coupon was set such that the value of the CDS contract at inception was zero, thereby requiring no upfront payment. However since 2009, contracts linked to each issuer now have a fixed coupon irrespective of when they were traded. As a result, the price of the credit risk is not reflected in the size of the coupon, but in the size of the upfront payment.

The exact details of how the premium schedule is calculated are beyond the scope of this section, although more information can be found in Chapter 67. However, it is worth noting that since 2008, the market standard is for contracts to trade with a full first coupon even if they are traded between two coupon payment dates. This enables a new contract to always have exactly the same cash flows as another existing contract with the same maturity date. This is discussed with specific examples in Chapter 67.

EXHIBIT 66–2

The Premium and Protection Legs of a CDS

Note: In this example we have a three-year CDS contract with quarterly coupon payments on the premium leg.

A key feature of the premium leg is that the payments terminate following a credit event. This is shown in Exhibit 66–2. All that is paid by the protection buyer on the premium leg is the amount of coupon that has accrued between the previous coupon payment date and the credit event. This feature of a CDS means that once a credit event has occurred, the premium leg terminates and the contract can be closed out.

The Protection Leg

The other leg of the CDS is the *protection leg,* also known as the contingent leg. This is the payment from the protection seller to cover the loss on the face value of debt, which is only triggered if there has been a credit event. Economically, the value of the payment equals par minus the recovery price of the deliverable obligations. Determination of the size of the recovery price or value is now done using a market-wide auction process that is discussed in detail below.

The market provides two mechanisms for the protection seller to effect the payment of protection. Either the protection seller can choose to pay a cash amount equal to par minus the recovery price determined by an auction, or the protection seller can request physical settlement, which means that they will pay the contract notional in cash and receive the corresponding face value of deliverable obligations at the price determined by the auction.

There are also two mechanisms for the protection buyer to receive the payment of protection. Either the protection buyer can choose to receive a cash amount equal to par minus the recovery price determined by the auction, or the protection buyer can request physical settlement, which means they will receive the notional amount in cash and deliver the corresponding face value of deliverable obligations at the price determined by the auction.

The protection buyer who elects for physical settlement can choose which deliverable obligations to deliver. They are long a "delivery option" whose value depends on the range of prices of the deliverable obligations. The protection seller who has chosen physical settlement has to accept what is delivered. This is discussed in more detail below.

The Upfront Payment

The cost of protection is paid for through both the payment of the fixed coupon on the premium leg of the CDS and through upfront payment. This is the cost which has to be paid in order to enter into the CDS contract and may be positive or negative. Whether it is positive or negative depends primarily on whether the party is buying or selling protection and how the market perceived credit quality of the reference credit compares with the fixed coupon on the CDS. The market perceived credit quality of the reference credit is captured by the CDS "quoted" spread, which is defined in detail in Chapter 67.

For example, consider a short protection CDS position on a credit that trades with a fixed coupon of 100 bp, but whose credit quality has recently deteriorated so that its CDS market quoted spread is currently 160 bp. This will require an upfront payment as the protection buyer will pay cash to the protection seller in order to offset the fact that the coupon is not high enough to compensate the protection seller for the market perceived credit risk of the reference credit. Before 2009, this contract would have had no upfront cost, as it would have paid a coupon of 160 bp.

Once a CDS has been traded, its mark-to-market value begins to change due to changes in the market view of the credit risk of the reference entity as expressed by the quoted spread and changes in interest rates.

For those familiar with the valuation of CDS contracts before the introduction of fixed coupons, the valuation and risk-management has not changed in any significant way. Once the contract has traded and the upfront payment made, the value of the contract looking forward is identical to before. For example, consider a long protection CDS contract with a coupon of 100 bp in which the current quoted spread is 160 bp. This will have a positive value for the protection buyer as he is paying only 100 bp for protection, which the market now considers to be worth 160 bp. However we do not have enough information to determine whether the position has a positive P&L (ignoring for a moment the impact of coupons paid) since this depends on the upfront value when the contract was entered into. Before the arrival of fixed coupons, the coupon on the CDS would have told us the spread when the

contract was initiated and as the initial cost would have been zero, the mark to market of the CDS would, excluding coupons, be the P&L of the position.

The valuation and risk-management of a CDS is covered in Chapter 67.

CREDIT EVENTS

The *credit event* is the term used by the credit derivative market to define each of the events that can trigger the payment of the CDS protection. Companies can default or enter into a restructuring. The situation is even more complicated for sovereign debt since countries do not formally file for bankruptcy. Instead they can default in a number of different ways, for example, by repudiating their debt or by re-denominating their foreign currency debt. The standard credit events used in CDS need to be broad enough to encompass this range of scenarios. A list of the main such credit events is provided in Exhibit 66–3.

In Exhibit 66–3 we have stipulated which credit events are "hard" and which are "soft." This designation refers to what happens to the debt obligations of the reference entity following the credit event. For most credit events, the debt becomes immediately due and payable. This means that all debt obligations, irrespective of maturity and coupon, which are *pari passu* with each other have an equal claim on the remaining value of the company and so should trade at the same price. These are what we call *hard credit events*.

EXHIBIT 66–3

The Main Credit Events Used in the CDS Market

Credit Event	Hard or Soft	Description
Bankruptcy	Hard	Corporate becomes insolvent or is unable to pay its debts.
Failure to pay	Hard	Failure of the reference entity to make due payments, taking into account some grace period.
Obligation acceleration	Hard	Obligations have become due and payable earlier than they would have due to default and have been accelerated. This event is used mainly in the case of emerging market sovereigns.
Obligation default	Hard	Obligations have become due and payable prior to maturity. This event is used rarely.
Repudiation/ Moratorium	Hard	A reference entity or government authority rejects the validity of the obligations. This is used for sovereign credits.
Restructuring	Soft	Changes in the debt obligations of the reference entity which result in a credit deterioration for the debt holders.

The Restructuring Credit Event

There is only one soft credit event. This is the event of restructuring in which a company does not file for bankruptcy but agrees with its creditors a consensual restructuring of its debt obligations, but in a way that has a negative impact for the creditors.

The restructuring credit event refers to out-of-court pre-insolvency restructuring that usually requires the unanimous approval of all impaired creditors. Since the company continues to trade as a going concern, debt does not become immediately due and payable. Therefore, a restructuring credit event does not cause all *pari passu* debt to trade at the same price and so the debt obligations continue to trade with prices that take into account a term structure, and coupon effects (i.e., higher coupon bonds trade at a higher price than lower coupon bonds of the same maturity.

The reason why we single out soft credit events is that they present a delivery option for the protection buyer. Recall that the protection buyer can choose which obligations they wish to deliver from a basket of possible deliverables. As the deliverable obligations continue to trade at different prices caused by different coupons and maturities, there may be some value in the delivery option, and the protection buyer will always be motivated to deliver the cheapest bond or loan he can find.

As a result, if the debt obligations held by the protection buyer are not the cheapest to deliver, it will be economically preferable to sell these in order to buy the cheapest to deliver, gaining the price difference as a windfall gain. The act of always delivering the cheapest deliverable causes the protection seller to take a larger loss than if another deliverable had been chosen.

Such a situation occurred following the restructuring of the debt of the U.S. insurer Conseco Inc. in 2000. In this case, banks which held short-maturity loans that were not particularly impaired by the restructuring, and who had bought CDS protection on these loans, were able to sell these loans for close to par and use the proceeds to purchase deep discount bonds trading in the $65 to $80 range, which they could then deliver in return for par. They were therefore able to make a windfall gain at the expense of the protection sellers.

Following this, complaints were made by Conseco protection sellers. This resulted in the introduction of a new clause that formed part of the revised CDS documentation released in 2001. Called the *modified-restructuring (Mod-Re) clause,* it was intended to reduce the value of the delivery option following a restructuring by reducing the range of deliverable obligations in the basket. This was done by restricting the maturity of the deliverable obligations. This clause only applied to the North American CDS market.

In 2003, Europe followed by introducing its own restructuring clause. As it was a variation of the North American clause, it was known as *modified-modified restructuring (Mod-Mod Re).* These regional differences were due to the differing requirements of the local financial regulators and the differing importance of banks versus investors in the different regions.

We now have three different restructuring clauses, each with its own restrictions on the maturity of the deliverables. These are as follows:

- *Old-Restructuring (Old-Re):* This is the pre-2003 standard which only imposes a 30-year maturity limit on deliverables.
- *Modified-Restructuring (Mod-Re):* The exact maturity limits of the Mod-Re deliverable obligations are quite complicated. A rough and ready approximation is that the deliverable obligations cannot have a maturity longer than the greater of the scheduled termination date of the CDS and the restructuring date plus 30 months. If we use RMLD to denote the restructuring maturity limitation date then

  $$\text{RMLD} = \text{Max}\ [\text{TD}, \text{RD} + 30 \text{ months}]$$

  where TD is the scheduled termination date of the CDS contract and RD is the date of the restructuring event.
- *Modified-Modified Restructuring (Mod-Mod Re):* This is similar to modified restructuring. The difference is that the formula for the restructuring maturity limitation date is given by

  $$\text{RMLD} = \text{Max}\ [\text{TD}, \text{RD} + \text{A}]$$

  where A equals 60 months for restructured obligations and 30 months for nonrestructured obligations.

There is a fourth alternative which is to remove restructuring from the list of credit events. This is simply called No-Restructuring (No-Re). The situation as of early 2011 is summarized in Exhibit 66–4.

EXHIBIT 66–4

The Standard Credit Events by Region for CDS and CDS Indices

Geographic Region	Credit Events in Standard CDS and CDS Index Contracts
North America*	Bankruptcy
	Failure to pay
Europe	Bankruptcy
	Failure to Pay
	Restructuring according to Mod-Mod Re
Asia	Bankruptcy
	Failure to Pay
	Restructuring according to Old-Re

*The Standard North American Contract is known as SNAC.

Settlement of a Credit Event

Ultimately, the post-credit event settlement of a CDS contract is all about determining the final recovery price for the deliverable obligations. This is done via an auction. The main objectives of the auction process are as follows:

1. To be able to handle cases in which the notional of protection bought approaches or exceeds the total outstanding notional of deliverable obligations. In this case there can be a short squeeze as protection buyers who do not own deliverables attempt to buy these obligations in order to settle their contracts. In the past this has led to the prices of deliverable obligations to rise after the credit event as protection buyers rush to buy them in order to deliver them.
2. To ensure that the recovery price is the same across the entire CDS market. This is necessary if market participants who are both long and short protection to the same maturity on a reference credit are to be sure that they will be hedged. This requires a common recovery price to be set via a public auction procedure described below.
3. To handle the soft restructuring credit event. Recall that hard credit events cause all of the *pari passu* debt obligations to trade at the same price. However following restructuring credit events the debt obligations continue to trade with a term structure and the value of this delivery option led to the introduction of the Mod-Re and Mod-Mod Re restructuring clauses as described earlier. The auction needs to be able to handle these restructuring clauses.

As we shall see, these requirements have all been met by the procedure that we now describe in detail.

THE CDS SETTLEMENT TIMELINE

We now set out the mechanics of settlement of a CDS contract once a credit event has occurred. Many important changes have been made to these mechanics over the past few years. To provide an overview, Exhibit 66–5 shows a timeline of the different stages that begin with credit event determination.

Credit Event Determination

Until 2009, the determination of whether a credit event had occurred was a bilateral decision that involved the protection buyer sending the protection seller evidence that a credit event had occurred. This evidence would consist of publicly available information such as newspaper or wire service reports of a bankruptcy,

EXHIBIT 66–5

Timeline for a Credit Event

failure to pay, or restructuring.[7] In most cases in which the source of the information was reputable and the events described clearly satisfied one of the specified credit events, the contract would trigger.

However, in cases in which the information was not public, was unclear, or was contested, there was a risk that different pairs of parties could come to different conclusions. This would be a problem for hedged intermediaries who would find

7. Or any other form of credit event included in the contract.

that one contract might be triggered but the offsetting contract would not, or that the recovery rate on one contract was not the same as the recovery rate on the offsetting contract, generating an unexpected gain or loss.

To address this concern, the market introduced a new credit event determination procedure as part of the legal protocols ushered in by the 2009 Big Bang. This introduced a new body known as the *determinations committee* (DC) that is tasked with the job of determining whether a credit event has occurred. In actual practice there are five such DCs, one for each of the following: the Americas, Asia (excluding Japan), Japan, Australia-New Zealand, and EMEA (Europe, the Middle East, and Africa).

In order to remove any bias and to ensure that decisions are not finely balanced, the membership of each committee consists of both buy-side and sell-side representatives, and the approval of decisions of the committee requires an 80% supermajority.

The credit event determination process begins when any market participant who has signed up to the new credit derivative protocols introduced in 2009 makes a request to the secretary of the DC to investigate whether a specific reference credit has experienced a credit event. This request should be accompanied by a notice of publicly available information reporting that a credit event may have occurred. The DC then has two business days to meet, investigate, and then vote on whether a credit event has occurred. If more time is needed, they can vote to extend this time period.

Once the credit event has been determined and it is a hard credit event, all CDS contracts linked to this reference credit are automatically triggered. This is a change from the pre-Big Bang procedure in which one of the parties to the CDS would choose to trigger the contract.

However if the credit event is determined to be a restructuring, either the protection buyer or the protection seller must choose to trigger the contract. Furthermore, the exact constituents of the basket of deliverable obligations depend on which party triggered first. This is discussed in more detail below.

The rationale for not making the triggering automatic is that restructuring is not a bankruptcy event but could be a precursor to one. As a result, a protection buyer may prefer not to trigger, thereby keeping the CDS protection "alive" for a later and possibly lower recovery hard credit event.

The Compression Cycle

One of the recent innovations of the credit derivatives market has been the use of what has become known as the "compression cycle." This is a procedure designed to enable groups of counterparties to cancel out mutually offsetting positions. This process is run periodically (typically once a quarter) across the entire credit derivatives market.

Although previously a rather ad-hoc procedure, it has also become an important stage in the settlement of a credit event, where it is run across the relevant CDS contracts after it has been determined that a credit event has

occurred and before the auction begins. However, this is only done for those contracts held by dealers who choose to participate in the compression cycle. The effect of running the compression cycle is to reduce the number of contracts that have to participate in the subsequent auction. This will reduce the amount of physical assets needed to settle the credit event.

The main provider of this compression service is a company called TriOptima. A third party is used to provide this service because compression is all about the cancellation of sets of contracts between three or more dealers. To do this, the parties either need to reveal their full positions list to each other or they need to involve a neutral third party. Dealers prefer the latter, and so introduce a third party to collect the information on the condition that they do not disclose position data to the other parties.

An algorithm is run that calculates the specific set of transactions that if executed would most reduce the outstanding number of contracts. These transactions are then reported back to the dealers who then can choose whether or not to execute them. Between 2008 and 2010, this compression process eliminated around $14.5 trillion of credit derivative contracts from the market.

Deliverables for a Nonrestructuring Credit Event

Within a short period of the credit event being determined by the DC to be a hard credit event, the DC publishes a timetable of when the credit event was determined, when the auction will be held and when the auction will be settled. A list of the deliverable obligations is also published.[8] For hard credit events, there is just one auction as there is just one basket of deliverables for all CDS contracts since the maturity limitation is at 30 years.

Deliverables for a Restructuring Credit Event

When the credit event is a restructuring, the situation depends on the region. In North America, there is no restructuring credit event in standard contracts and so there is only one auction. In Asia, the use of the old-restructuring convention means that there is only one basket for all contracts. In Europe, the situation is more complicated. The market standard is to include a restructuring credit event. However the standard restructuring clause is modified-modified restructuring in which the basket of deliverables depends on the scheduled termination date of the CDS contract.

The purpose of the standard modified-modified restructuring clause found in European CDS contracts is to limit the basket of deliverables in order to reduce the value of the delivery option. In approximate terms, the restructuring maturity limitation date for a deliverable into a CDS contract with a scheduled termination date (TD) is given by

$$\text{RMLD} = \text{Max}\ [\text{TD}, \text{RD} + 60\ \text{Months}]$$

8. All of this information is publicly available on the ISDA website: http://www2.isda.org/.

for restructured obligations, and

$$\text{RMLD} = \text{Max [TD, RD + 30 Months]}$$

for nonrestructured obligations. In both cases the basket of deliverables depends mainly on the TD of each CDS contract.

Reconciling this restructuring clause with an auction mechanism presents an immediate difficulty. If the reference credit has a large number of deliverable obligations distributed across the maturity spectrum, it is possible that there will be a different basket of deliverable obligations for each possible CDS scheduled termination date. Given that the longest maturity CDS contracts have a scheduled termination date in around ten years, and given that CDS scheduled termination dates are quarterly, this implies that we could have more than 30 distinct baskets of deliverables[9] for a given reference entity. However, holding this many auctions in parallel would be organizationally burdensome. It would also split the universe of relevant contracts across many auctions, resulting in a loss of liquidity and price competition in each auction.

To overcome this problem, the market has decided to run a maximum of eight different auctions by assigning each CDS contract to one of eight maturity buckets. The buckets and what they contain are listed in Exhibit 66–6. In practice, fewer than eight buckets may be used if a lack of deliverables across the maturity spectrum means that two or more buckets are identical. In this case only the earliest of these buckets will have an auction. In addition, a minimum liquidity requirement states that an auction will only be held if 300 or more contracts

EXHIBIT 66–6

The Maximum Set of Auction Buckets Used after a Restructuring Credit Event

Bucket
Nonrestructured debt obligations out to 30 months and restructured debt obligations out to 5 years;
All deliverable obligations to 5 years;
All deliverable obligations to 7.5 years;
All deliverable obligations to 10 years;
All deliverable obligations to 12.5 years;
All deliverable obligations to 15 years;
All deliverable obligations to 20 years; and
All deliverable obligations to 30 years.

9. Out to 30 months there is just one bucket according to Mod-Mod Re. Beyond 30 months, the remaining deliverable buckets depend on the contract scheduled termination date. These are quarterly so for example could be in 33, 36, 39, …, 120 months giving a total of 1 + 30 = 31 buckets.

linked to that bucket are triggered and if there are five or more dealers who are party to these transactions.

If a bucket is not used, then the protection buyer and seller have a *movement option*. This allows the protection buyer to choose to move the contract to use the next earliest maturity bucket. The protection seller also has a movement option and can also choose to move the contract to the longest maturity 30-year bucket. If both parties wish to exercise the movement option, then the protection buyer's decision is the one that takes priority.

Prior to the auction, each CDS contract must be assigned to one of these buckets. To simplify matters, one of the duties performed by the DC is to calculate and publish a table that maps ranges of scheduled termination dates to specific buckets. However, there is one final step before CDS holders know which maturity bucket, and hence which auction, is relevant to their contract. This is the triggering decision.

Restructuring: Triggering a Credit Default Swap

Unlike hard credit events, the triggering of a contract following a restructuring credit event is not automatic. In fact it is actually asymmetric in the sense that the basket of deliverable obligations depends on which party, if any, is the first to trigger the contract. The rules are as follows:

- If the contract is triggered by the protection buyer, then the basket that applies is the one that corresponds to the scheduled termination date of the CDS contract.
- If the contract is triggered by the protection seller, then the basket that applies is the longest maturity (30-year) basket.

The consequence of these rules is that each party wants the other to trigger. To see why, consider the holder of five-year CDS protection. He will prefer the protection seller to trigger because the 30-year bucket contains more deliverable obligations than the five-year bucket, and so the value of the delivery option is greater. At the same time the protection seller wants the protection buyer to trigger since he does not wish to be delivered a long-dated obligation.

However, the protection buyer also knows that if he fails to trigger within the specified period, the ability to trigger for this credit event is lost. This is known as *use it* or *lose it*. Suffice to say that both protection buyers and sellers will usually wait until the last moment to trigger. However, great care needs to be taken not to miss the triggering deadline altogether.

There is another complicating factor, which is that the decision period for the protection buyer and seller are not always the same. Typically these periods begin together, but the protection buyer has five days, whereas the protection seller has three days to decide.[10]

10. A discussion of all of the issues is beyond the scope of this chapter. For more information, see Dominic O'Kane, "Testing the Protocols," Nomura International Fixed Income Research, March 2010.

If the contract is not triggered by either party, it does not follow that the protection is lost altogether. It just means that it cannot be used for this credit event but can be used for any subsequent credit event.

The Auction Process

Before the auction, holders of CDS contracts need to decide whether they wish to use cash or physical settlement. A protection buyer who elects for physical settlement will end up with par in cash and a short position in the deliverable obligation after the auction. This replicates the economics of delivering a bond to the protection seller in return for par. Equally a protection seller who elects for physical settlement will end up paying par in cash and owning a deliverable obligation. This replicates the economics of paying par and taking delivery of a deliverable obligation from the protection buyer.

The auction breaks the link between the protection buyer and seller since each party to a CDS can each choose a settlement mechanism that may be different to that of their counterparty.

Prior to the auction, market participants who wish to have physical settlement are able to submit physical settlement requests via their dealers. These must arrive before 5 p.m. on the day before the auction. Each request must be in line with the market participant's net CDS position (i.e., a net long protection position must correspond with a request to sell bonds, and vice versa).

A protection seller will choose physical rather than cash settlement in order to realize a view that the current recovery price is too low and will rise after the auction. This view requires the protection seller to hold the physical asset.

The auction is a two-stage process that is administered by Creditex and Markit. It is carried out via the Creditex inter-dealer electronic trading platform. This means that non-dealers cannot participate directly but must do so via their chosen dealer. Both stages occur on the same auction date, with stage one usually occurring in the morning and stage two in the afternoon.

Auction: Stage One

Stage one of the auction is used to determine an indicative recovery price for the deliverable obligations and the net open interest to buy or sell physical assets that will be used in stage two of the auction. Stage one is limited to parties who have CDS positions and have submitted physical settlement requests.

The process is short, lasting only 15 minutes. In this time, the participating dealers submit two-way bid/offer prices for the deliverable obligations. At the same time, the dealers submit physical settlement requests on behalf of their customers and on their own behalf. Note that there is a maximum limit on the bid/offer spread submitted by dealers that prevents dealers from making uncompetitive markets. There is also a minimum trade size. Both of these constraints are set in advance by the DC and are a function of the liquidity and market outstanding notional of the reference credit.

At the end of this 15-minute period, the auction administrator has a further 15-minute period during which they calculate and then publish the indicative recovery price. This is more formally known as the internal market midpoint price (IMMP) and is calculated using an algorithm that rejects outlying price combinations (to prevent manipulation) and averages the remaining bid/offer spreads that are then rounded to the nearest 1/8th of a point. The internal market midpoint price will then be used in stage two of the auction procedure to constrain the final auction price.

The final calculation is the net open interest, which is simply the aggregation of the physical settlement requests. This establishes the size and direction of the demand of market participants to use physical settlement, i.e., the total amount of deliverable obligations to be traded in stage two of the auction and whether the net open interest is to buy or sell these deliverable obligations.[11]

Auction: Stage Two

Stage two of the auction occurs when the parties bid to satisfy the net open interest determined in stage one. This process results in a market-wide recovery price that is then used to settle all CDS contracts, including both those that are cash and physically settled.

Stage two begins two or three hours after the end of stage one, thereby giving market participants time to decide how to respond to the results of stage one. Unlike stage one it is an auction that is open to all parties who have signed up to the ISDA protocol, not just those who hold a CDS position in the relevant reference entity. This maximizes the number of participants and should maximize the chances of a competitive auction.

If the net open interest of stage one of the auction is to sell bonds, then the aim of stage two is to match this open interest with those who wish to buy the bonds. If the net open interest of stage two of the auction is to buy bonds, then the aim of stage two of the auction is to find bond sellers.

At the start of stage two, auction participants have a 15-minute window during which they submit limit orders of a size that is only limited by the size of the net open interest. The order prices can be at whatever price they decide. To do so, they have to commit that they will be willing to transact the limit order size of deliverable obligations at the final auction price.

When this period is over, an order matching algorithm is run on all of the submitted orders. If the open interest was to buy bonds, then the auction is one in which participants submit offer prices to sell bonds. The open interest is then filled starting at the lowest price until all of the open interest has been filled. The price at which this happens is the final auction price. If the open interest was to sell bonds, then the auction is one in which participants submit bid prices to buy bonds. The open interest is then filled starting at the highest price

11. The open interest, the various bids and offers and the calculated internal market midpoint price are all published on the www.creditfixings.com website.

until all of the open interest has been filled. The price at which this happens is the final auction price.

This final auction price may not become the official final auction price, as there is a condition that requires that the final price be within a certain range, known as the *cap amount,* of the IMMP calculated in stage one. If the final auction price is above the IMMP by more than the cap amount, then it is set equal to the IMMP plus the cap amount. If the final auction price is below the IMMP by more than the cap amount, then it is set equal to the IMMP minus the cap price.

After the auction, dealers are paired off with each other so that the demand to buy or sell deliverable obligations that were submitted in the first stage of the auction can be satisfied by the demand to satisfy the open interest that was filled by the orders submitted in the second stage of the auction. The dealers then in turn enter into trades with their customers to satisfy their physical settlement requests, and the settlement procedure is then complete.

CDS INDICES

Following the CDS, the most important product in the credit derivatives market is the CDS index. Unlike CDS, CDS indices are primarily used by investors to easily obtain a diversified credit exposure as they enable an investor to take a broad exposure to the credit market in a single transaction. The upfront cost required to enter into a CDS index is usually a small percentage of the notional and this makes it possible to leverage the risk of a CDS position. CDS indices are also used as a way to hedge the credit risk associated with a broad portfolio of credit names. This can be useful for credit funds, hedge funds, or banks wishing to hedge the so-called systemic market credit risk.

The first CDS indices appeared in 2002 to the extent that there were competing index providers in each regional market. This situation persisted until the middle of 2004. At this time the North American indices fell under the name CDX, while their European and Asian equivalents fell under the name iTraxx. The main CDS indices that now trade are listed in Exhibit 66–7. Of these the most liquid are the North American and European investment-grade indices, known as CDX IG and iTraxx Europe, respectively.

Note that in the CDS index market, "buying the index" means assuming the credit risk by selling protection and receiving the coupon. This differs from the CDS market, in which "buying" generally means buying protection. It is worth noting that the CDS indices are equally weighted when issued. This differs from stock indices, which are either market cap-weighted or price-weighted. It also differs from the traditional fixed income benchmark indices found in the credit markets, which are almost always weighted by the outstanding debt of each issuer. This was done for reasons of simplicity and to maximize diversification. However, this can change during the life of an index if one or more companies in the index splits (de-merges) or two or more of the companies in the index merge.

CDS Index Constituents

A CDS index is essentially a portfolio of CDS in which the credits in the index satisfy a certain set of inclusion criteria. For example, the CDX IG index is the CDS index, which contains the 125 most liquid investment-grade (IG) credits that trade in the CDS market and are domiciled in North America. The main inclusion criteria for the main CDS indices are shown in Exhibit 66–7.

At any moment in time, there is not just one of each of the CDS indices trading in the market but several series. This is because a new series of each CDS index is issued every six months. Although the new version of the index will have the same credit inclusion criteria as the whole series, the actual credit names of each series of the index may differ if certain credits were upgraded or downgraded, defaulted, or became less liquid since the previous issue date. The most recently issued series of any index is known as the "on-the-run" and is usually the most liquid.

There is also a further subdivision of a CDS index series by maturity. On the issue date, new series of a specific index are issued with terms which will typically include one, three, five, seven, and ten years. The maturity date of the *T*-year index will be on one of the standard CDS Dates—March 20, June 20, September 20, and December 20.

EXHIBIT 66–7

The Standard CDS Indices Showing the Type and Number of Credits in Each

Name	Domicile and Type of Credits	Number of Credits
CDX.NA.IG	North American investment-grade	125
CDX.NA.HY	North American high-yield	100
CDX.NA.XO	North American crossover[12]	35
CDX.EM	Emerging market sovereign	15
CDX.EM.Diversified	Emerging market sovereign/corporate	40
iTraxx Europe	European investment-grade	125
iTraxx Europe Crossover	European crossover	40
iTraxx Japan	Japanese investment-grade	50
iTraxx Asia ex-Japan	Asian non-Japanese investment-grade	50
iTraxx Australia	Australian investment-grade	25

12. The term *crossover* refers to credits that were initially investment-grade but have since been downgraded to subinvestment-grade.

For a series that rolls on March 20 and September 20 each year, the corresponding maturity dates will be June 20 and December 20 T years later. This means that the time to maturity of the term T index will actually be T years plus three months at issue and this will have fallen to T years minus three months by the time the next series of the index is issued six months later. This allows an investor to continuously roll his index position into the next "on-the-run" index and so be able to maintain his average maturity at close to T years.

CDS Index Mechanics

To enter into a CDS index, the buyer (or protection seller) pays an upfront cost. The value of this may be positive or negative, and so may actually result in a payment to the index buyer. This depends on the size of the fixed coupon paid by the index and the current trading level of the index.

Each series of a CDS index has its coupon set on the issue date, and this coupon is fixed thereafter. It is usually set at a value that makes the initial upfront value of the index close to zero. Once the index series has been issued, changes in the market perceived credit quality of the index causes the upfront value to change. This is exactly analogous to the mechanics of the CDS market, in which contracts linked to each specific reference entity adopted a fixed coupon in 2009.

The economics of a CDS index are identical to those of a portfolio of CDS contracts where the coupons on the CDS contracts equal the index coupon. As with a CDS, there is both a premium leg and a protection leg.

The Premium Leg

The premium leg of a CDS index is the payment of the coupon to the buyer of the index. The actual payment amounts are determined by multiplying the index fixed coupon by the day count fraction[13] that has elapsed since the previous coupon date and then by the *surviving notional* of the index reference portfolio. The surviving notional at initiation is the contract notional. However, over time this may change if there are credit events.

As credits in the reference portfolio experience credit events, the surviving notional of the index is reduced in proportion to the number of credits remaining. So if two credits in a reference portfolio of initially 125 credits experience a credit event, the surviving notional of the index is 123/125 times the initial notional and the size of the coupon is also reduced to 123/125 times the initial coupon. Note that the notional does not depend on the size of the recovery rate of the defaulted credits, just the number of credit events.

The economics of a CDS index premium leg are therefore equivalent to that of a portfolio of CDS premium legs linked to each of the reference credits in the index, which all pay a fixed coupon equal to the index coupon. The premium leg

13. The day count fraction is usually calculated according to an Actual 360 basis convention.

is paid until the end of the contract, the exception being the unlikely case of all of the credits in the reference portfolio experiencing a credit event.

The Protection Leg

The protection leg of the CDS index is identical to that of an equally weighted portfolio of CDS protection legs on the reference portfolio. If a credit event occurs on a reference credit in the index, the index buyer must pay the index seller the loss on that credit. The process is as follows:

1. The credit is immediately removed from that index series across all maturities.
2. The new index without the credit is thereafter assigned a new version number to distinguish it from earlier versions of the index series.
3. The reference credit that was removed then becomes a standalone CDS position with the notional corresponding to its notional size in the index, e.g., if the index position size was $10 million and there were 125 credits in the index, then the notional of the standalone CDS contract will be $80,000.

The standalone CDS position then takes part in the standard auction procedure as described earlier. In economic terms, this will result in the index buyer having to pay the index seller par minus the auction recovery rate on the CDS notional.

There is an added complication if the credit event was a restructuring. In this case, the index buyer and seller have the option to trigger the standalone contract. If they both choose not to trigger, then the standalone CDS position continues to sit on their respective books until maturity or until it is triggered by a subsequent credit event. However, this is usually only a consideration for European and Asian index holders since, as shown in Exhibit 66–4, the standard for North American indices is to exclude restructuring as a credit event.

IMPORTANCE OF THE CDS MARKET

The credit derivatives market has become an important branch of the credit markets. The ease with which a single-name CDS can be traded has made it an invaluable hedging tool for many, most notably bank loan risk managers. The CDS index has also become an important investment tool for credit investors seeking to quickly and easily obtain a macro-level credit exposure.

In the aftermath of the financial crisis of 2008, the market quickly responded with a number of fundamental changes in the format and mechanics of the contract to increase fungibility and so decrease counterparty risk. The triggering and settlement of credit events were revised to ensure that there is a common market-wide process and to minimize the risk of failing to settle.

Many of the changes were intended to facilitate making all market participants face centralized counterparties (CCPs) rather than dealers in an attempt to reduce the systemic risk associated with the default of a major dealer. This process began in 2009 and by February 2011, one of the major clearing houses, the ICE Trust in North America and ICE Clear in Europe, had together cleared more than $15 trillion of credit derivatives, of which over 80% were CDS indices.

One area of valid criticism of the market was its opaqueness pre-2008, which was unsurprising given the OTC nature of credit derivative transactions. The publication of high-level position data by the New York-based DTCC who are responsible for CDS settlements has added a new level of transparency with respect to market size, the reference entities being traded and the different types of counterparties.

A recurring pattern of the credit derivative market has been that each time there is a credit crisis that exposes any flaws in the mechanics of the market, the market moves quickly to attempt to eliminate such flaws so that the same problems will not recur. This reflects the importance that the market attributes to a well-functioning credit derivatives market. As a result, the market is now better settled, more transparent, less exposed to systemic risk, and better regulated than it has ever been.

KEY POINTS

- The credit derivatives market is dominated by the single-name credit default swap (CDS) and the CDS indices.
- The growth of the CDS and CDS index market has been driven by its many uses. These include transferring credit risk, hedging credit risk, isolation of credit risk, leveraging and yield enhancement, structured credit investments, and managing regulatory risk.
- The simplest way to think of the CDS is as an insurance contract in which one party, the "protection buyer," pays a premium to be protected against a credit loss on a specific face amount of bonds or loans issued by a specified corporate or sovereign reference entity.
- The other party to the CDS, known as the "seller of protection," receives the premium and takes on the credit risk. The protection seller makes a contractual payment to the protection buyer if a credit event occurs during the tenure of the contract.
- The "credit event" is the term used by the credit derivative market to define each of the events that can trigger the payment of the CDS protection. Credit events may include bankruptcy, failure to pay, obligations acceleration, repudiation/moratorium of debt, and restructuring of debt.

- The event of restructuring is a "soft" credit event since debt can continue to trade with a term structure after a restructuring. Since this can create a potentially valuable "delivery option" for protection buyers, it is excluded from the standard CDS contract on North America-domiciled companies. However, regulatory and other differences mean that it is included in standard contracts on Europe- and Asia-domiciled companies.
- To avoid a "short squeeze" following a credit event and to ensure that the same recovery rate is used across the market, the CDS market has introduced an auction process in which holders of the relevant CDS engage and only the net amount of deliverable obligations need to be physically traded.
- Credit default swap indices are equally weighted portfolios of up to 125 CDS that can be traded in one single highly liquid transaction. The CDS index market provides asset managers with a highly liquid way to assume or hedge an exposure to market-wide or sector-wide credit risk.
- Following the financial crisis of 2008–2009, the credit derivative market made a number of substantial reforms in order to ensure a well ordered market-wide settlement mechanism following credit events, to improve transparency and reduce systemic risk via the use of centralized counterparties.
- A CDS or CDS index contract can be sold at any time before maturity, allowing the owner to realize any gain or loss resulting from changes in the market perceived credit quality of the reference entity.

CHAPTER
SIXTY-SEVEN

CREDIT DERIVATIVE VALUATION AND RISK

DOMINIC O'KANE, D.PHIL. (OXON)
Affiliated Professor of Finance
EDHEC Business School

The purpose of this chapter is to set out the valuation methodology for credit swaps (CDS) and CDS indices. As described in Chapter 66, a credit default swap (CDS) is the most commonly traded credit derivative contract. It is also the building block for the CDS indices. An understanding of the valuation and risk management of CDS is therefore essential if we are to understand the valuation and risk management of CDS indices and other credit derivatives.

CDS VALUATION

For valuation purposes the essential features of a CDS contract are as follows:

- A regular fixed coupon is paid on the premium leg from the protection buyer to the protection seller according to a frequency and basis convention as set out in Exhibit 67–1. The coupon is paid until contract maturity date or a credit event, whichever occurs first. If the credit event occurs between two coupon payment dates, the market standard convention is that the portion of the coupon that had accrued from the previous payment date until the Event Determination Date[1] must be paid by the protection buyer.
- A payment of par minus the recovery rate is paid following a credit event. The recovery rate is set at the auction (which was described in Chapter 66) and paid shortly after on the auction settlement date.

We therefore have future cash flows which are contingent on a credit event. The CDS value is given by the expected present value of these flows calculated in the "risk-neutral" measure (i.e., using probabilities of a credit event that exactly reprice the term structure of market prices of quoted CDS).

The author acknowledges the helpful comments from Samuel Morgan and Mark Ames.

1. This is the date the question to determine a credit event was submitted to the determinations committee (DC).

EXHIBIT 67–1

Standard CDS Contract Specifications for North American and European Markets

Specification	North America	Europe
Maturity Date	CDS dates unadjusted	CDS dates unadjusted
Accrual Dates	CDS dates adjusted except for maturity date	CDS dates adjusted except for maturity date
Payment Dates	CDS dates that are holiday adjusted	CDS dates that are holiday adjusted
Coupons	100 bp and 500 bp	25 bp, 100 bp, 500 bp, and 1,000 bp
Frequency	Quarterly	Quarterly
Day Count Basis	Actual/360	Actual/360
Pay Accrued on Default	Yes	Yes

The precise rules which generate the schedule of premium leg payments are listed in Exhibit 67–1. The CDS dates referred to in this Exhibit are March 20, June 20, September 20, and December 20.

Need for a Model

The pricing and risk management of a CDS contract requires the use of a pricing model. There are a number of reasons for this:

1. The CDS market is OTC. As such, there is no central location where trades are executed from which prices can be instantly reported. Prices are instead agreed bilaterally and privately. Market pricing providers such as Markit[2] only provide end-of-day pricing based on aggregating pricing submissions from various dealers.
2. Even if CDS contracts were exchange-traded, the quotation of prices would be complicated by the fact that there are so many different variations in the contracts outstanding. Consider just those contracts written against a single reference entity and assume that the longest maturity contract is 10 years and that all contracts trade with the same coupon and credit events. Since maturity dates are on a quarterly schedule, we can have as many as 40 different contracts being traded, albeit with varying degrees of liquidity. Quoting so many numbers per issuer can be cumbersome. A model that allows pricing based on a smaller number of market inputs is certainly preferable.

2. www.markit.com.

3. Although there is the concept of a standard CDS contract, market participants can request customized features which may deviate from this standard. For example, a company may wish to buy a forward CDS contract in which protection starts at some future date. To price this correctly relative to other CDS, a model is required that must also reprice the current market prices.
4. A valuation model is also important for risk management. With bonds, we need, at the very least, to introduce the concept of a yield-to-maturity and yield-curve before we can start to hedge the interest rate risk of a bond portfolio with other bonds. The same is true with a portfolio of credit default swaps. A model is needed in order to be able to quantify spread risk and to hedge the credit risk sensitivity of one CDS against another.

The value of a CDS contract is simply the upfront value at which the CDS contract should trade. For a protection seller, this is equal to the expected present value of the incoming coupons on the premium leg minus the expected present value of the protection leg. For a protection buyer, it is the negative of this since the protection buyer is receiving the protection but paying the coupons.

Even without a model, we can begin to think about the factors that affect the CDS value. We consider the two legs separately:

1. The value of the premium leg is the expected present value of the coupons paid until maturity or a credit event, whichever happens first. If the credit quality of the reference credit falls then this will make an early credit event more likely and so it is more likely that not all of the coupons will be received. The expected present value of the premium leg will then fall. Also, as it is an annuity of fixed coupons, its present value will also fall if interest rates rise. The value of the premium leg also increases with CDS maturity since more coupons are to be paid.
2. The value of the protection leg increases if the credit deteriorates since it becomes more likely that the payment of par minus the recovery rate will be received. It will also increase with increasing contract maturity as protection for a longer period is always more valuable than for a shorter period. However, it falls as interest rates increase since it is the present value of a future contingent payment.

Before we move on to describe a model that can value each of the legs, we first wish to show that it is possible to actually determine the no-arbitrage value of the upfront cost of protection by reference to the cash bond market.

THE CDS–BOND RELATIONSHIP

Subject to a number of important assumptions, there is a fundamental no-arbitrage relationship between the upfront value of a CDS and the price of a specific floating rate bond issued by the same reference entity. Specifically, our aim is to

show that there is an exact relationship between the upfront cost of a time T maturity CDS, U, and the price P of a floating rate note with a time T maturity where the floating rate note pays a floating rate coupon equal to LIBOR plus a spread C. This spread must be equal to the fixed spread of the CDS. We need to consider the following trading strategy:

1. At time zero, an investor borrows an amount $P + U$ at a funding rate of LIBOR. This assumes that the investor has a credit quality similar to that of highly rated commercial banks. This funding is locked in until future time T. Interest payments are made quarterly.
2. At time zero, the investor uses P of the borrowed money to buy one unit of face value of a time T maturity floating rate note issued by the reference entity at a specific seniority. The full price of this bond is P. For simplicity we assume that the purchase begins on a coupon payment date so that there is no accrued interest to consider.
3. At the same time, the investor uses U of the borrowed money to buy CDS protection on one unit of face value of the reference entity that matures at future time T. Note that U can be positive or negative. Following this, the now hedged investor will have to make quarterly coupon payments.

To analyze this strategy, we need to determine the payments at four different types of event: (1) initiation, (2) coupon payment dates, (3) following a credit event, and (4) maturity time T (assuming that no credit event has occurred). These are shown in Exhibit 67–2.

For simplicity we assumed that the credit event occurs on a coupon payment date so that the repayment of the funding simply costs par, i.e., the face value of the borrowing, which in this case is $(P + U)$, and so that there is no coupon accrued to be paid on the CDS.

As the initial net cash-flow is zero—the strategy costs nothing to enter—the expected value of the future payments should equal zero. For this to be true, we require that $P + U = 100\%$, i.e., there is a fundamental no-arbitrage relationship

EXHIBIT 67–2

No-Arbitrage Strategy of Bond plus CDS Protection

Time	Funding	Bond	CDS	Net
Initiation	$P + U$	$-P$	$-U$	0
Coupon Dates	$-(P + U)\Delta L$	$(L + C)\,\Delta$	$-C\Delta$	$-(P + U)L\Delta + L\Delta$
Credit Event	$-(P + U)$	R	$(100\% - R)$	$100\% - (P + U)$
Maturity	$-(P + U)$	100%	0	$100\% - (P + U)$

between the upfront cost of the CDS and the price of a floating rate note issued by the same reference entity. For example, if the LIBOR floater is priced at par, then the upfront value is zero. However if the LIBOR floater is worth more than par, then the upfront cost of protection is negative. If the LIBOR floater is worth less than par, then the upfront cost of protection is positive.

In order to establish this relationship, we have had to make a number of simplifying assumptions. The main ones are:

1. We assumed that the bond buyer funded at LIBOR flat and that funding at this level can be locked in until the maturity of the CDS. In practice, the funding of the bond will be done in the repo market where it will generally not be possible to lock-in the funding level for any extended period. The hedged investor therefore has funding risk, which can work for or against them. There may also be a haircut on the amount funded and this depends on the market risk of the bond, which is used as collateral in the repo.
2. We assumed the existence of a T-maturity *pari passu* floater, which pays LIBOR plus C where C is equal to the fixed spread of the CDS contract.
3. We ignored the effect of the delivery option, which could allow the protection buyer to deliver a cheaper bond (if one exists). This is most likely to be of value if the CDS includes restructuring as a credit event. The value of this option should make the cost of protection higher.
4. We assumed that the credit event falls on a coupon payment date. In practice a default between coupon payment dates will mean an additional payment by the protection buyer of the accrued coupon on the CDS. For the bond, it may mean that the unpaid coupons are added to the bondholders' claim in bankruptcy.
5. We ignored the effect of counterparty risk on the CDS. Counterparty risk is typically mitigated by the posting of upfront collateral.
6. We ignored tax effects that may treat the coupon and principal differently.
7. We ignored transaction costs and market technical effects. In the latter case, we note that since the CDS market makes it easier to short credit risk, any negative news on a credit will typically impact the CDS market first, causing the CDS upfront price to increase before bond prices fall.

What we have done here is to establish a link between the upfront costs of CDS and the pricing of a specific bond issued by the same reference entity. However, in practice, this is not a viable way to price CDS contracts since it is almost certain that the required T-maturity *pari passu* floater, which pays a spread equal to the coupon on the CDS, does not exist. Also, the list of assumptions means that although there is a strong relationship between bond prices and CDS upfront costs, the relationship is not exact.

The CDS Basis

The difference between the cash and CDS market is known as the CDS basis. It is defined as

$$\text{CDS Basis} = \text{CDS Par Spread} - \text{Bond LIBOR Spread}$$

This is not an exact definition since there are various ways to quote the bond LIBOR spread.[3] One LIBOR spread widely used by the market is the asset swap spread of a bond of the issuer with a similar maturity to the CDS, which is trading at a price close to par.

Trading the CDS basis has become a relative value strategy of a number of credit investors, in particular credit hedge funds. The aim of basis trading is to determine which of the assumptions listed above is driving the difference between CDS spreads and bond spreads and to take a view on whether these are correctly or incorrectly priced and liable to change.

The standard basis trade is the "negative basis trade" in which the investor buys the bond and buys protection. It is called a negative basis trade because the investor receives the bond spread and pays the CDS spread—the investor receives negative of the basis as defined above.

Valuation of an Existing Contract

Consider an investor who sells protection using a five-year CDS contract at time zero. The upfront cost, which is the amount paid in cash to enter the contract is $U(0)$. In return, the investor receives a regular coupon C and we call the expected present value of this the value of the premium leg. He also has to pay the counterparty $(1 - R)$ on the face value of the protection if there is a credit event between the effective date and the contract maturity time. The expected present value of payment is the value of the protection leg. We can therefore state that $U(0)$ is the cost of this where

$$U(0) = V_{\text{Premium}}(0,5) - V_{\text{Protection}}(0,5)$$

This is at initiation. Subsequently, at time t, the value of the premium leg and protection legs will change as coupons are received, maturity approaches and the market's view of the default risk of the reference credit changes. At this time the value of the contract is given by

$$U(t) = V_{\text{Premium}}(t,5) - V_{\text{Protection}}(t,5)$$

One year later, the investor wishes to unwind his position. Given that he sold protection, he must now buy protection. The cost of entering into the long protection position is given by $-U(1)$ where

$$U(1) = V_{\text{Premium}}(1,5) - V_{\text{Protection}}(1,5)$$

3. These include the asset swap spread, the par floater spread, the discount margin and the zero volatility spread.

Since the coupon dates and any contingent protection payments on this new contract match exactly the coupon payment dates and any contingent protection payment on the existing contract, the combined position has future cash flows equal to zero. The mark-to-market value of this short protection CDS position at any time is therefore simply the upfront cost of buying protection to the same maturity as the initial contract. This is different from the P&L which is the money earned or lost by first selling protection and then closing out the trade one year later by buying protection. This is equal to the upfront cost $U(1)$ which was received plus all of the rolled-up coupon payments minus the cost of repaying any initial loan $U(0)$.

Market Pricing

The pricing of CDS is done with reference to the spreads at which the current market standard contracts trade. These are for contracts which terminate at the main maturity points, which include six-months and one, two, three, four, five, seven, and 10 years. The market has two conventions for quoting spreads. They are:

1. Par Spreads: The T-year par spread is defined as the coupon that would be paid for protection on a T-year contract *which has no initial cost.*
2. Flat Quoted Spread: The T-year flat quoted spread is defined as the level at which a flat CDS par spread curve needs to be marked in order that the model-implied upfront value matches the upfront value quoted in the market. It therefore ignores the shape of the term structure of the CDS market—it is the CDS equivalent of the bond yield-to-maturity.

The par spread was the quotation convention for the CDS market until 2010. The "problem" with the par spread is that calculation of the upfront value requires knowledge of the full term structure of par spreads of quoted CDS contracts with the same or shorter maturities. Therefore, several par spreads may be needed to calculate one CDS upfront value and one CDS upfront value cannot be used to imply a term structure of par spreads. As a result, the quoted flat spread has become the market standard. Its existence is based on a need to have a spread-based quotation for the price of a CDS contract. Use of the quoted flat spread also entails using the market standard recovery rate assumption, which is currently set at 40% for senior unsecured debt.

Because the quoted spread convention assumes that the spread curve is flat, there is a one-to-one mapping (based on the pricing model that we will describe below) between the T-year maturity quoted flat CDS spread and the upfront cost of a T-year CDS contract. Note also that if the par spread curve is actually flat, then the quoted flat spreads will all be the same for all maturity points and par and quoted flat spreads will be equal.[4] In order to assist clarity, we will be using the notation in Exhibit 67–3 to denote these different coupons and spread measures in what follows.

4. This presumes that the same recovery rate assumption is used.

EXHIBIT 67–3

Notation for Spreads and Coupons

Symbol	Description
$C(T)$	The coupon of a T-year maturity CDS contract.
$U(t)$	The upfront value of a T-year maturity CDS contract at time t.
$S(t, T)$	The time t par spread paid on a T-year maturity CDS contract that has no initial cost.
$\bar{S}(t, T)$	The "quoted" spread is the level of a flat par CDS spread curve that sets the model-implied upfront cost of a T-year CDS equal to its market value at time t.

MODEL

To value a CDS, we need a model. This model must satisfy the following requirements:

1. It must capture a credit event as a single event that can occur at any future time.
2. It must capture the timing of the default and the fact that the market may expect the future default rate to be a varying function of time, i.e., it can have a term structure.
3. It must capture the payment of par minus the recovery rate following a credit event.
4. It must be able to reprice the term structure of market prices exactly.
5. It must be fast to calibrate to the market and fast to price.

The standard model in the market is based on the use of the survival probability $Q(T)$. This is the probability that the reference credit survives without experiencing a credit event from today (time zero) to time T in the future. The value of $Q(T)$ must be between 0 and 1, and must be a constant or decreasing function of T.

Valuation of the Premium Leg

The premium leg of a CDS is the payment of the fixed coupon that continues at quarterly intervals until a credit event or maturity, whichever occurs first. Each coupon is therefore a conditional payment—conditional on the reference entity surviving until the coupon payment date. We also need to discount these future

conditional coupons at the LIBOR rate. If we assume that the premium leg has N remaining coupons, we can write

$$V_{\text{Premium}} = C(T)\sum_{i=1}^{N} \Delta(t_{i-1}, t_i) Z(t_i) Q(t_i)$$

That is, for each payment date we multiply the fixed coupon $C(T)$ by the year fraction $\Delta(t_{i-1}, t_i)$ since the previous coupon payment date in the corresponding basis.[5] We then weight it by the probability of the reference entity surviving to the coupon payment date by multiplying by $Q(t_i)$. We finally discount it back to today at the LIBOR rate using the discount factor $Z(t_i)$.

By itself, this equation fails to take into account the coupon accrued that has to be paid if there is a credit event between coupon payment dates as it assumes that the CDS only pays a coupon if the reference credit survives up to the coupon payment date. An exact calculation of the value of the contribution of the coupon accrued is beyond the scope of this chapter. However, we can approximate the value of the contribution by simply assuming that if the reference credit experiences a credit event in the period before the coupon is paid, it will on average occur in the middle of the period. In this case, the amount of accrued coupon will be

$$\frac{C(T)\Delta(t_{i-1}, t_i)}{2}$$

i.e., one half of the full coupon. The probability of defaulting in the period before the coupon is due to be paid is given by $Q(t_{i-1}) - Q(t_i)$. For simplicity and without any significant loss of accuracy we can assume that this is then paid at the end of the period. We therefore have a coupon accrued contribution given by

$$\frac{C(T)}{2}\sum_{i=1}^{N} \Delta(t_{i-1}, t_i) Z(t_i)(Q(t_{i-1}) - Q(t_i))$$

Adding this to the value of the premium leg above gives

$$V_{\text{Premium}} = \frac{C(T)}{2}\sum_{i=1}^{N} \Delta(t_{i-1}, t_i) Z(t_i)(Q(t_i) + Q(t_{i-1}))$$

We can rewrite this as

$$V_{\text{Premium}} = C(T)A(T)$$

5. The market standard is Actual/360. Care needs to be taken since in practice there may be a difference between the accrual dates and the actual payment dates. In particular the actual final payment date at maturity is usually holiday/weekend adjusted while the final accrual date is not.

where

$$A(T) = \frac{1}{2}\sum_{i=1}^{N} \Delta(t_{i-1}, t_i) Z(t_i)(Q(t_i) + Q(t_{i-1}))$$

The quantity is known as the risky annuity. It is the expected present value of the premium leg assuming it pays an annualized coupon of \$1 and any accrued fraction of this coupon if there is a credit event. It is a function of the entire shape of the survival curve since each premium payment is weighted by the survival probability to the premium payment date.

Value of the Protection Leg

The protection leg pays $(1 - R)$ at the time of a credit event.[6] To find the present value of this we have to take into account when the payment occurs. We need to split the time between today and the end of the contract into lots of small intervals and determine the probability of defaulting in each small time period and then discount the payment back to today.

Suppose we split the time between now, time 0, and the maturity date in T years into M such intervals of length T/M. The value of the protection is then given by

$$V_{\text{Protection}} = (1 - R)\sum_{n=1}^{M} Z(t_n)(Q(t_{n-1}) - Q(t_n))$$

where $(1-R)$ is the amount paid following a credit event, which we assume does not depend on the timing of the credit event, and $Q(t_{n-1}) - Q(t_n)$ is the probability of defaulting between time t_{n-1} and t_n.

In practice, the value of M must be a large number in order to best capture the full shape of the survival probability curve and the discount curve. However, it cannot be too large otherwise it would become numerically slow to price a CDS contract.[7]

The Upfront Cost

Here we define the upfront cost as the cost which must be paid by a protection buyer to enter into a CDS contract. It is therefore the expected present value of the protection leg minus the expected present value of the premium leg; that is, it is given by

$$U(0) = V_{\text{Protection}} - V_{\text{Premium}}$$

6. Strictly speaking, payment occurs on the settlement date of the post-credit event auction. The two steps in the auction are described in Chapter 66.
7. A discussion of appropriate values for M is provided in Dominic O'Kane, *Modelling Single-Name and Multi-name Credit Derivatives* (John Wiley & Sons, 2008).

where

$$V_{\text{Premium}} = \frac{C(T)}{2}\sum_{i=1}^{N}\Delta(t_{i-1},t_i)Z(t_i)(Q(t_i)+Q(t_{i-1})) = C(T)A(T)$$

and

$$V_{\text{Protection}} = (1-R)\sum_{n=1}^{M} Z(t_n)(Q(t_{n-1})-Q(t_n))$$

These are all at time 0.

The Upfront and the Par CDS Spread

The T-year par spread $S(T)$ is the value of the coupon on the T-year CDS, which makes the current value of the contract equal to zero. Therefore

$$S(T)A(T) - V_{\text{Protection}} = 0 \Rightarrow V_{\text{Protection}} = S(T)A(T)$$

But the value of the contract at time zero using its actual coupon is

$$U(0) = V_{\text{Protection}} - C(T)A(T)$$

and we can substitute in the protection leg value to write this as

$$U(0) = \big(S(T) - C(T)\big)A(T)$$

The situation changes when we calculate the value of the contract using the flat spread. This is simply defined via the equation

$$U(0) = (\bar{S}(T) - C(T))\bar{A}(T)$$

This equation looks almost identical to the par spread valuation above. However there is one major difference. The value of the risky annuity here is only a function of the quoted flat spread $\bar{S}(T)$, whereas the value of the risky annuity using the par spread is a function of the *term structure of par spreads*. Clearly, the quoted flat spread does not take into account the term structure of spreads.

Interpolation of the Survival Curve

Before we can use this model, we must calibrate it to the term structure of market prices. This can mean a number of things. It could mean calibrating it to a term structure of upfront costs, a term structure of par spreads, or a term structure of flat spreads. Whichever it is, we will usually have market price data at maturity points starting at six months and then up to 10 years in annual steps. To use these 11 market prices to calibrate a term structure of survival probabilities we need to simplify the term structure of survival probabilities so that it is described by

exactly 11 variables. Then we will have one unknown variable for each piece of data and we should then be able to fit exactly the market prices using this simplified term structure.

There are many ways to do this simplification. The market standard is to introduce the continuously compounded forward default rate $h(t)$. This is defined in terms of the survival probability as

$$Q(T) = \exp\left(-\int_0^T h(t)dt\right)$$

A common simplification is to assume that this continuously compounded forward default rate is piecewise flat as shown in Exhibit 67–4.

Given 11 market prices, the term structure of this continuously compounded forward default rate takes 11 different values: $h(0.5)$, $h(1.0)$, $h(2.0), \ldots, h(10)$, where each $h(t)$ is the value of the continuously compounded forward default rate from the previous time to time t. We then have

$$Q(0.5) = \exp(-0.5 \times h(0.5))$$
$$Q(1) = Q(0.5) \times \exp(-0.50 \times h(1.0))$$
$$\ldots$$
$$Q(10) = Q(9.0) \times \exp(-h(10.0))$$

EXHIBIT 67–4

Piecewise Flat Term Structure of the Forward Default Rate in Which We Calibrate to the 6M, 1Y, 2Y, ..., 10Y CDS Upfront Prices

However, the power of this approach is that it allows us to interpolate the value of the survival curve to other times. So for example we have

$$Q(0.3) = \exp(-0.3 \times h(0.5))$$
$$Q(0.7) = Q(0.5) \times \exp(-0.20 \times h(1.0))$$
$$Q(1.9) = Q(1.0) \times \exp(-0.90 \times h(2.0))$$

The whole term structure of survival probabilities is determined by these 11 values of the continuously compounded forward default rate. As long as the value of $h(t)$ is greater than or equal to zero, the term structure of CDS spreads will be arbitrage-free.[8]

Calibration by Bootstrap

Given the model and this interpolation scheme, we need one more input before we can calibrate the values of the continuously compounded forward rates to the market prices of CDS. This is the value of the expected recovery rate R. Note that this does not have to be the same value as the one used by the market to convert the flat quoted spread to an upfront and back which is currently set equal to 40%. It can be a value chosen by the model user.[9] With all of this information, the calibration can then be performed. This is done using a bootstrap.[10] The process is as follows:

1. Search for the value of $h(0.5)$ for which the model-implied upfront value equals the market quoted upfront of the six-month contract given the fixed coupon. As there is one unknown and one price, we should be able to determine $h(0.5)$ so that the market price is fitted exactly.
2. Using $h(0.5)$, now search for the value of $h(1.0)$ for which the model implied upfront equals the market quoted upfront of the one-year contract given its fixed coupon.
3. Repeat step two for each next longer maturity CDS, each time using knowledge of all the previously calibrated values of $h(t)$ to calculate the next one.

8. A term structure of CDS spreads can exhibit an arbitrage if the value of the protection leg to time T_1 is greater than the value of the protection leg to time T_2 where $T_2 > T_1$. In some cases this can allow for a strategy which can guarantee a positive income at no initial cost.
9. The effect of choosing a different recovery rate is that although the model will be calibrated to the market prices of quoted CDS contracts, the value of the protection and premium legs taken separately may differ from the value of the protection and premium legs according to the market standard recovery rate assumption.
10. A bootstrap is the name given to an algorithm that recursively solves a system of coupled equations one at a time, with each solution being found only after a set of the previous parameters have been found.

At the end of this process, we should have a value of h for each market price. From this we are able to compute the market-implied value of $Q(T)$ to any future time T. The value of $Q(T)$ that emerges from our market calibration is the "risk-neutral" survival probability. By risk-neutral, we mean the probability that, according to our model, reprices the market prices of CDS spreads—any other set of probabilities would not reprice the market and hence could create arbitrage possibilities. These spreads are credit-specific, forward-looking measures of the compensation required by a protection seller to sell protection until time T.

It is generally found[11] that credit spreads overcompensate the investor for the expected loss based on the incidence of default of other credits that had the same credit rating. There are a number of reasons why this may be the case. Mainly it is because the market is forward looking and may not consider historical default probabilities, especially when averaged over an economic cycle, to be appropriate given the current state of the economy. Also, because there is typically a large systemic and hence nondiversifiable component to credit spreads, investors demand an additional premium.

NEW AND EXISTING CONTRACTS

The price calculated by a CDS valuation model is the full price, i.e., the cash amount actually paid for the protection. One of the contractual details which determines this value is the date when the contract starts accruing the premium. In order to improve market fungibility of CDS contracts, the standard is for all new contracts to have a full first coupon; i.e., they begin accruing from the previous coupon payment date even if the contract was traded and settled more recently. This makes all contracts with the same maturity date identical in term of their cash flows. It also means that a hedger who buys protection mid-payment period will have to pay for protection that was not received and should expect to be reimbursed for this through the value of the upfront payment. After all, the upfront cash amount to be paid to enter into this contract for protection is the expected present value of the protection leg minus the expected value of the premium leg. This premium leg will include a full first coupon.

The simplest example we can use to examine the effect of this is to assume that the CDS has a fixed coupon of 100 bp and the par spread to the same maturity is also at 100 bp. However, the par spread is based on a CDS contract which starts accruing at $T + 1$, i.e., one day after the trade date, which must by definition have zero upfront value. Calibration of our CDS model determines the survival probability curve that ensures that this is the case. In more general terms, the value of the same maturity CDS used to calibrate the CDS valuation model is given by:

$$U_{Calibration}(t) = V_{Protection} - C(T)A(t,T) = 0$$

11. For a literature review. see John Hull, Mirela Predescu, and Alan White, "Bond Prices, Default Probabilities and Risk Premiums," *Journal of Credit Risk* 1(2) (2005), pp. 53–60.

If we then use this curve to price our existing contract, we will find that the value of the contract will be

$$U_{Contract}(t) = V_{Protection} - C(T)A(t_0, 0)$$

where t_0 is the time of the previous coupon. But we can then write

$$A(t_0, T) \approx A(t, T) + \Delta(t_0, 0)$$

which should be a very good approximation.[12] This gives

$$U_{Contract}(t) = V_{Protection} - C(T)A(t, T) - C(T)\Delta(t_0, 0)$$

The first two terms on the right-hand side equal the value of the CDS contract we are calibrating to which is zero, and so we have

$$U_{Contract}(t) = -C(T)\Delta(t_0, 0)$$

This is the negative of the coupon which has accrued since the previous coupon date. The protection buyer therefore finds that the contract pays him for the portion of coupon which accrued since the last coupon date which he has to pay on the next payment date, but whose benefit he did not enjoy since he wishes to enter the contract today. Clearly the payment of the coupon can be up to three months in the future (this is offset by the fact that the further in the future the coupon payment occurs the less that has accrued) while the upfront cost is paid on the settlement date which is trade date plus three days, holiday adjusted. For this reason, setting the value of the contract equal to the negative of the accrued coupon is a good approximation but one that would only be exact in a world of zero interest rates.

There is one more issue to consider—the CDS contract provides protection against a credit event which occurred between T-60 and today. If such an event has been determined by the Determinations Committee (see Chapter 66) then the CDS contract would be in its post-credit event settlement process and the upfront cost would be close to par minus the expected recovery rate. If the event has not been determined, the implicit assumption is that market expectations that a credit event occurred in the past 60 days are already priced into the CDS spread curve.

RISK MANAGEMENT

We now wish to understand the factors that drive the valuation of a CDS contract. Specifically, we want to be able to calculate the hedge ratios needed to ensure that the value of a portfolio of CDS contracts on the same reference credit is immunized

12. It is based on the observation that any already accrued coupon will either be paid on the next coupon date if there is no default or it will be paid immediately if there is a default. In this sense it is a risk-free payment made at some point in the short period between today and the next coupon date. Since the period is short we can almost always ignore the time-value issue and not discount it.

against parallel moves in the CDS spread curve and the LIBOR interest rate curve. We begin by writing the time t upfront value of a (short protection) CDS contract as

$$U(t,S(t,T)) = \big(C - S(t,T)\big)\,A(T,S(t,T))$$

where $S(t, T)$ is the time T maturity par CDS spread as seen at time t. Note that we have inserted an explicit par spread dependency into the upfront value and the risky annuity term $A(T, S(t, T))$ to remind ourselves that a change in the par spread followed by a recalibration will cause the term structure of survival probabilities to change and so will change the present value of the risky annuity and the value of the upfront.

Spread DV01 of a CDS

The credit duration of a CDS contract is usually known as the Spread DV01. It is defined as the change in the upfront value of the contract for a 1 bp parallel bump upwards in the CDS spread curve. For a short protection position, we can write this as

$$\text{Spread DV01} = U(t,S+1bp) - U(t,S)$$

This gives

$$\text{Spread DV01} = -A(T,S+1bp)\cdot 1bp + (S-C)\cdot\big(A(T,S) - A(T,S+1bp)\big)$$

There are two contributions to the Spread DV01:

1. The first term describes a fall in the upfront value of the short protection position by $A(T, S + 1\ bp)$ times the change in the spread. The value falls because we have sold protection and the credit quality of the reference credit, as implied by the spread which was bumped, has worsened so the position has lost value.
2. There is a second term due the fact that the change in spread also causes the value of $A(T, S)$ to change. Because this term is multiplied by the spread difference $(S - C)$, it is usually much smaller then the first term. Also, the sign of the change is driven by the sign of $(S - C)$. If this is positive, it means that this term will offset the effect of the first term and reduce the Spread DV01. If negative it can increase the Spread DV01.

The Spread DV01 of a short protection position is therefore typically close in value to the negative of the risky annuity given by $A(T, S)$ multiplied by 1 basis point and approaches[13] it if $S = C$. The spread sensitivity from the perspective of a long protection position is simply the negative of that of a short protection position.

Hedging different CDS positions using the Spread DV01 is only really effective if the quoted spread or par spread of the different contracts move by

13. It does not equal it exactly, since when $S = C$ the Spread DV01 equals –A(S + 1) and not –A(S).

the same amount. For contracts of differing maturity, this requires the CDS curve to move in parallel shifts, which is not always the case. For this reason, use of the Spread DV01 should generally only apply to contracts of a similar maturity. To go beyond Spread DV01, we would need to calculate the sensitivity of a CDS contract to movements of different curve points (e.g., one year, three year, five year, seven year, and 10 year), and determine the set of positions in each of these contracts needed to immunize the hedged portfolio against spread movements.[14]

Interest Rate Duration of a CDS

The interest rate sensitivity of a CDS contract is known as its IR DV01. It is defined as the change in the upfront value of the contract for a 1 bp parallel bump upwards in the LIBOR curve while keeping the par spread curve fixed. As the only interest rate dependency is in the annuity term, we have

$$\text{IR } 01 = (C - S) \cdot (A^*(T) - A(T))$$

where $A^*(T)$ is the value of the risky annuity calculated using the bumped interest rate curve. Since this is the present value of future cash flows, we can conclude that $A^*(T) - A(T) < 0$. We can therefore conclude that: (1) if $C = S$ the interest rate sensitivity of a CDS is zero, (2) if $S < C$ then the IR DV01 is negative, and (3) if $S > C$ then the IR DV01 is positive.

In general the interest rate sensitivity of a CDS is low, especially when compared with a fixed-rate corporate bond with the same maturity date. This is due to the fact that the bond has coupons plus a payment of par at maturity, while the CDS is effectively a credit risky annuity with annualized coupon payments of $(C - S)$ and unlike a bond there is no payment of par at maturity. In fact the interest rate sensitivity of a CDS actually close resembles the interest rate sensitivity of a same-maturity par floating rate note issued by the reference entity.

Example

Exhibit 67–5 shows an example[15] of the pricing of a real CDS trade to buy protection until March 20, 2016. The CDS coupon (deal spread) has been fixed at 100 bp. The pricing of the CDS is captured by the current flat spread, called the "quoted spread," to the contract maturity date, which is 34.32 bp. This is the only spread quote needed to determine the upfront value. Both the deal and the quoted spread assume the market standard recovery rate of 40%.[16]

14. This procedure is discussed in detail in O'Kane, *Modelling Single-Name and Multi-name Credit Derivatives.*
15. The valuation here reproduces that produced by the standard CDS valuation calculator found on Bloomberg, which is accessed via the code CDSW.
16. These would only differ if the user was attempting to price a fixed recovery default swap.

EXHIBIT 67–5

The Value of the CDS Contract

Trade Description			
Notional:	$10m	Trade Date:	3rd February 2011
Maturity:	20 March 2016	Settlement:	8th February 2011
Buy/Sell:	Buy Protection	Quoted Spread:	34.32 bp
Deal Spread	100 bp	Currency:	USD
Valuation Results			
Price	103.22035	Accrued	–$12,778 (46 days)
Principal	–$322,035	Spread DV01:	5,036.41
Cash Amount	–$334,813	IR DV01:	84.26

We explain the valuation outputs in Exhibit 67–5:

- **Price:** This is the "clean" price for a protection seller who was to buy the CDS together with a par LIBOR floating rate note. It excludes the payment of accrued interest that would need to be added to the actual price paid.
- **Principal:** This is the clean (excluding accrued interest) value of the contract. It is computed by subtracting the accrued interest from the cash amount defined below.
- **Accrued Interest:** This is the amount of coupon that has accrued since the last coupon payment date or the first accrual date. For a new contract and an existing contract this is always the CDS Date that falls before the trade date. For a protection buyer the accrued interest is always negative while for a protection seller it is always positive. The valuation shows 46 days of a 100 bp coupon that has accrued from the previous payment date on 20 December 20, 2010 to T+1 calendar, which falls on February 4, 2011.
- **Cash Amount:** This is the actual upfront amount that has to be paid to enter into this contract. The valuation is –$334,813 meaning that the protection buyer receives $334,813 to enter into this contract. This is because the protection buyer who enters into this contract has to pay an annualized coupon of 100 bp for up to five years for a reference entity with a quoted flat spread of 34.32 bp. Because the coupon being paid is higher than the cost of protection implied by the quoted spread, the protection buyer has to be compensated upfront.
- **Spread DV01:** The spread sensitivity of the long protection position is calculated to be $5,036, meaning that a 1 bp increase in the quoted spread curve would cause the value of the CDS position to increase by this amount.

- **IR DV01:** The interest rate sensitivity of the contract is also positive, but much smaller at $84.24. This makes it very clear that a CDS is almost purely a credit-spread product.

Exhibit 67–6 shows the cash flows on the premium leg of the CDS. We see the payment dates and the corresponding amounts calculated using the Actual 360 day count convention. We also see the discount factors implied by the LIBOR deposit rates and swap rates used. Finally we see the survival probabilities

EXHIBIT 67–6

Mon 21 Mar 2016	25,277.78	0.888739	0.970749	0.029251

implied by our CDS valuation model. The default probability is simply one minus the survival probability.

Approximation

For those wishing to evaluate trading strategies, the Bloomberg pricer found under CDSW can be limiting and a simple Excel-based pricer would be quite useful, even if it is not exact. It is therefore worth describing a simple approximation that is based on the observation that the value of the risky annuity of a new CDS contract can be linked directly to the quoted flat spread $\bar{S}$ and the recovery rate assumption R using the following approximation

$$A(\bar{S},T) \approx \frac{1-\exp\left(-\left(\mathrm{W}+\frac{\bar{S}}{(1-R)}\right)T\right)}{\mathrm{W}+\frac{\bar{S}}{(1-R)}} \times \frac{365}{360}$$

where W is the swap rate to the contract maturity in T years and the ratio of 365/360 is used to adjust for the Actual 360 convention used to determine the size of premium payments.[17] The value of a long protection CDS position is simply given using the standard valuation equation:

$$U(t) = \left(\bar{S} - C\right) A(\bar{S},T)$$

Taking the example above where the quoted spread is 34.23 bp, the time from today to contract maturity is 5.122 years and the 5-year swap rate is 2.4%, we find that

$$A(\bar{S},T) = \frac{1-\exp\left(-\left(0.024+\frac{0.003432}{(1-0.4)}\right)\cdot 5.122\right)}{0.024+\frac{0.003432}{(1-0.4)}} \times \frac{365}{360} = 4.81764$$

We therefore calculate

$$U_{Existing}(t) = \$10,000,000 \cdot \frac{(34.32-100)}{10000} \cdot 4.81764 - \$12,778 = -\$329,992$$

This should be compared to the cash amount calculated by the Bloomberg valuation (not shown) which was –$334,813, a difference of about $5,000 on a $10 million face value. Note that we had to subtract the 46 days of accrued coupon which have

17. Using an Actual 360 basis the sum of the actual coupon payments over a year exceeds the amount implied by the annualized coupon by this ratio in non-leap years. Any good approximation of the risky annuity needs to account for this.

to be paid by the protection buyer at the end of this coupon period. These are worth \$12,778. The reason for doing this is that this contract requires the protection buyer to pay a full coupon on the next payment date. However the quoted spread of 34.32 bp is for a contract that starts accruing from T + 1. To account for this we need to compensate the protection buyer for having to make this extra future payment and to a very good first approximation, this can be done by subtracting the accrued coupon. The valuation is within 1.5% of the Bloomberg result—corrections to the interest rate used to discount the CDS cash flows to account for the slope in the swap curve can further improve the accuracy of this approximation.[18]

CDS INDEX VALUATION

The mechanics of the CDS index have been set out in Chapter 66. We showed that a CDS index is equivalent to a portfolio of CDS in which the individual CDS all pay the same index coupon given by $C_I(T)$. In this section, we wish to show that for valuation purposes a CDS index can actually be treated as though it were a CDS contract. We recall from Chapter 66 that the buyer of a time T-maturity CDS index is selling protection on a portfolio of P different time T-maturity CDS contracts, and receiving a coupon $C_I(T)$ in return for assuming this risk. Credit events in the portfolio result in the relevant CDS being removed from the index and settled via the standard auction procedure described in Chapter 66.

On each coupon payment date the size of the coupon payment is proportional to the size of the remaining portfolio of CDS. It therefore falls in absolute terms as credit events occur.

Therefore, unlike a single-name CDS, a CDS index does not have a single credit event which causes it to pay out a single loss and then cancel. Instead, the contract remains active[19] until maturity, with loss payments being made as and when credit events occur.

Index Valuation

From the perspective of an index buyer (protection seller), the CDS index value is equal to the premium legs of the P underlying CDS contracts that each pay the index coupon, minus the expected present value of the P protection legs. Using the notation set out in Exhibit 67–5, we can therefore write the value of the index premium leg as

18. The main reason for the difference is the upward sloping swap curve in February 2011, which rises from 0.46% at six months to 2.4% at five years. This is not consistent with our assumption of a flat swap curve. Using a maturity-weighted average swap rate of 1.67%, we obtained a valuation with an error of less than 0.1%.

19. Strictly speaking, the CDS index contract would cancel if all of the credits in the reference portfolio experienced a credit event. However given that the reference portfolio usually consists of 50–125 individual credits, the probability of this happening within the lifetime of a typical CDS index contract is considered to be close to zero.

EXHIBIT 67–7

Notation Used in the Valuation of CDS Indices

Symbol	Description
$C_I(T)$	The coupon of a T-year maturity CDS index.
$U_I(T)$	The upfront value of a T-year maturity CDS index.
$S_I(T)$	The par spread paid on a T-year maturity CDS index which has no initial cost.
$S_P(T)$	The par spread paid on a T-year maturity CDS on reference credit p.
$\bar{S}_I(T)$	The "quoted" spread is the level of a flat par CDS index spread curve which sets the model-implied upfront cost of a T-year CDS index equal to its market value.

$$\frac{C_I(T)}{P}\sum_{p=1}^{P} A_p(T)$$

We can also write the value of the index protection leg in terms of the individual CDS spreads as

$$\frac{1}{P}\sum_{p=1}^{P} S_p(T)A_p(T)$$

We are assuming here that the reference credits are all equally weighted.[20] The value of the index (short protection) position is then

$$V^{Index} = \frac{1}{P}\sum_{p=1}^{P}(C_I(T) - S_p(T))A_p(T)$$

The most common application for CDS index pricing is Bloomberg's CDSW function. This treats a CDS index as a standard CDS contract. As with CDS, price quotations for the CDS indices are almost exclusively done using the "quoted" flat index spread defined as the level at which we would mark a flat CDS index par spread so that, when using the standard CDS pricing model, it would cause the index model price to refit the market upfront index price. We therefore have

$$V^{Index} = \frac{1}{P}\sum_{p=1}^{P}(C_I(T) - S_p(T))A_p(T) = (C_I(T) - \bar{S}_I(T))\bar{A}_I(T)$$

20. This is always the case on the issue date of an index. However, if one or more company splits or merges then this could cause some reference credits to have a smaller or larger notional than the others. Even if this does occur, it does not affect any of the index pricing analysis presented in this chapter.

The point here is that this mapping of a CDS index onto a single CDS contract allows us to use our single-name CDS analytics to value and risk manage the CDS index. By doing so, we price the CDS index as though it has its own index survival probability $Q_I(t)$. Note that if we assume that the expected recovery rates of all of the credits in the index are the same, we can write

$$Q_I(t) = \frac{1}{P}\sum_{p=1}^{P} Q_p(t) = N_I(t)$$

where $N_I(t)$ is the expected surviving notional of the index at time t. We do not use this relationship in pricing because it assumes that all recovery rates are the same, which is not always the case. However, in general, it is approximately true and does provide some intuition about the interpretation of the index survival probability.

The CDS Index Basis

If this relationship is not obeyed, there is then a theoretical mispricing. However, this theoretical mispricing may not be arbitrageable for a number of reasons:

1. Model prices are usually mid-market. Therefore, if we take into account the cost of crossing the bid-offer spread that would need to be done to monetize any mispricing, this mispricing may not be a real arbitrage opportunity after all.
2. Obtaining accurate and contemporaneous flat spreads for all of the constituents of a CDS index may not be possible.
3. Where CDS and CDS indices trade with different restructuring clauses, the replication is not exact and this relationship should not be exactly obeyed.

Despite these caveats, CDS indices have traded away from their CDS-implied spread. This will generally be due to market technical factors such as a market demand to buy or sell systemic versus single-name credit protection. If the deviation becomes large enough to be arbitraged, then hedge funds and other market players will step in to monetize the profit until their activities eliminate the arbitrage.

Risk Management

Since the CDS index contract is valued as though it was a single-name CDS contract, its price sensitivities are identical to those of a single-name CDS contract with the same term structure of par spreads or quoted spread, the same recovery rate, the same maturity and the same interest rate environment. As a result, we refer the reader to the section on CDS risk management.

KEY POINTS

- Since the introduction of fixed coupons for CDS contracts in 2009, entry to a CDS contract almost always involves some initial upfront cash payment, which can be positive or negative.
- From the perspective of a protection seller, the size and sign of the initial cash value of the contract depends on whether the fixed coupon is sufficient to compensate the protection seller for the market perceived risk of a credit event. If the coupon is low, the protection seller may receive cash at trade initiation. If the coupon is high, the protection seller may have to pay cash at trade initiation. The situation is reversed for a protection buyer.
- The purpose of the valuation of CDS and CDS indices is to calculate this upfront cash payment. This requires a model in order to determine the expected present value of the premium and protection leg of the contract.
- This model needs to take into account the probability of and the timing of a credit event. For the premium leg, it needs to take into account the risk that not all coupons will be paid. For the protection leg it needs to value the unknown payment of par minus recovery made at the time of the credit event, if one occurs. It also needs to be flexible enough to exactly reprice the term structure of quoted market spreads.
- One type of market quote is the CDS par spread. This is the value of the coupon that would need to be paid on the premium leg of a CDS in order for the contract to have zero upfront value on trade date. The value of a CDS is a function of the term structure of CDS par spreads.
- Since 2011, the CDS market has also begun to use an alternative measure known as the flat "quoted" spread. This is the level at which a flat term structure of par spreads would need to be set in order that they reprice the market quoted upfront value. As a result, only one quoted spread is needed to value a CDS contract.
- The probability of a CDS experiencing a credit event as implied by CDS market spreads usually exceeds the historical default probability implied by the default rate of credits that were initially assigned the same credit rating. This is because spreads are forward-looking and embed a risk premium.
- The model allows the holder of a CDS position to calculate the sensitivity of the value of the contract to changes in the quoted spread and so enables him to hedge it with other CDS contracts.
- For valuation purposes, a CDS index can be treated as a single-name CDS and valued and risk-managed using the same model as the CDS.

CHAPTER
SIXTY-EIGHT

HEDGING TAIL RISK

STEPHEN J. ANTCZAK, CFA

The recent financial crisis has created an increased focus on "tail risk" and ways to minimize exposure to the unexpected. Once the domain of risk managers and fringe thinkers on trading desks, it has become a common phrase among the lexicon on trading floors. For that matter, it is a common phrase even away from trading floors (e.g., Google "tail risk" and one may be surprised at the number of hits received). In fact, a number of hedge funds have recently been created solely to take advantage of tail risk.

In this chapter, we first discuss why tail events seem to occur with such regularity. We find that one or all of three characteristics (leverage, transient funding, and the influence of "noneconomic" objectives and constraints on investment decisions) are associated with many, if not most, tail events. We then provide some background on three specific tail risks that we "hedge" later in the chapter. These are a sharp decline in the equity market, public sector fiscal imbalances, and an economic downturn. It is important to recognize that we define an equity market downturn as a risk for fixed income investors in part because of the high correlation between stocks and segments of the fixed income market. The co-movement between the equity market and the high-yield sector of the credit market from May 2001 to May 2010 is shown in Exhibit 68–1. In addition, many bond investors, and for that matter investors in general, tend to view both opportunities and risks in a cross market context far more now than in years past.

With regard to constructing hedges, we next highlight four key challenges that most hedges face: (1) correlation between the portfolio being protected and the hedge vehicle itself, (2) cost, (3) the potential for slippage, and (4) the reliance on historical relationships, as these relationships can be transitory over time. We then consider two very broadly defined hedging strategies—unfunded and funded approaches—and note that both types typically face the challenges highlighted above (Exhibit 68–2). We define unfunded hedges as those for which an investor

This chapter was written when the author was the Head of U.S. Credit Strategy at Société Générale. The author would like to thank Jung Lee and Sandeep Mody for their assistance in developing this chapter.

Note: As of March 14, 2011.

is willing to dedicate a certain amount of capital to protect the portfolio. In some respects, unfunded strategies are comparable to insurance policies. Funded strategies tend to be utilized by market participants who are unable or unwilling to pay the cost of insurance outright. They nonetheless require a hedge, and therefore want (or need) to go long an asset to pay for insurance. Funded hedges tend to

EXHIBIT 68–2

Select Characteristics of Unfunded and Funded Hedges

	Unfunded Hedges	Funded Hedges
Definition	Investors dedicate capital to protect portfolios	Long exposure is used to pay for the cost of insurance
Primary concern	Loss prevention	Cost, asymmetric payoff profile, loss prevention
Goal	Protect portfolios against a wide variety of events	Protect an asset against a fairly specific problem with a "high" chance of occurring
Hedge modeling	History (to a large extent)	Scenario analysis (to a large extent)
Key concerns (albeit not all)	Cost, correlation, slippage, reliance on historical relationship	Cost, correlation, slippage, reliance on historical relationship, introduction of additional risks due to more "moving parts"

become more popular when the catalyst for a market setback is difficult to predict, as performance can lag if a premium is continuously being paid to protect against an event that does not occur. We assess the performance of various hedging vehicles in the context of a declining stock market tail event.

We then assess the effectiveness of various funded packages in the contexts of the second (sovereign credit event) and third risks (economic downturn). Finally, we discuss trade-specific hedge risks, such as counterparty risk. We find that funded hedges can be more risky than unfunded approaches, in large part because they have more "moving parts," but they are not necessarily less effective.

STEP-BY-STEP GUIDE TO HEDGING

There is no perfect hedging vehicle or approach, but we do believe that a checklist consisting of the following six steps can be fairly useful when constructing one.

- *Step One. Decide whether to hedge.* A credit portfolio manager sees a high likelihood of a tail event occurring. Does this mean that he should necessarily hedge? Perhaps, but not necessarily, as there are a number of factors that could warrant not hedging. Suppose that this portfolio manager handles 25% of an endowment's capital. What happens if the endowment also expects a tail event and shifts the 75% of funds that are not handled by this credit manager into cash? If the credit manager also hedges, the endowment may very well be overhedged. Or what if the portfolio manager anticipates a sharp pickup in defaults, but comes to this conclusion *after* the consensus does? It may already be priced in and therefore not cost effective (Exhibit 68–3).

EXHIBIT 68–3

U.S. Speculative-Grade Default Rate versus High-Yield Bond Index

Source of data: SG Cross Asset Research, Bloomberg, Moody's.

Note: As of January 31, 2011.

Default rates are LTM matched with one year back.

- *Step Two. Decide what to hedge.* Even if an investor decides that it is worthwhile to hedge, it is almost as important to understand exactly what is to be hedged. One type of tail event (e.g., sovereign default) could require a very different type of hedge than another (e.g., BP oil spill).
- *Step Three. Identify challenges to watch out for.* There are a number of challenges that could have some influence on the efficiency of virtually all hedge vehicles. These include the correlation between the hedging vehicle and the asset being hedged, the cost of the hedge, the potential for slippage between the hedged asset and the hedge itself, and the reliance on historical data to anticipate potential future performance.
- *Step Four. Decide whether to fund or not.* Given that hedges are in some ways comparable to insurance policies, an important choice must be made with regard to how to pay the premium. One could simply dedicate a certain amount of capital to pay for insurance and "write off" the premium. The downside, though, is that it is quite possible to underperform benchmarks or competitors if a tail event does not occur. Conversely, one could fund the hedge by going long an asset that is less sensitive to a tail event than the hedge, but there is a tradeoff as new risk factors can be introduced.
- *Step Five. Craft an efficient hedge.* Finding an efficient hedge to a large extent involves balancing the payoff potential in the event of a tail scenario with challenges such as cost. In addition, one can often use scenario analysis to identify downside risk with which one is comfortable.
- *Step Six. Identify trade-specific risks.* While we identified four generic challenges that can influence the typical hedge, there can be a number of trade-specific risks that are important to consider as well. For example, some hedges may have significant counterparty risk, liquidity can be far more of a factor for some hedges than others, etc.

THE NEED TO HEDGE

In theory, tail risk should happen infrequently—the once-in-a-lifetime storm, so to speak—but reality may be a bit different than theory. In Exhibit 68–4 we present a sample of some catalysts for major downturns from 1990 to 2010. The exhibit shows that we have seen catalysts for major downward moves fairly frequently—essentially every three years or so.

While there is no single reason that can account for what seems to be relatively frequent tail events, three ingredients do seem to be well represented among most observations—excess leverage (be it financial, operational, or the like) combined with unstable access to funding and potentially noneconomic investment objectives/constraints. Events ranging from the Russian default to the U.S. real estate bubble shared some of these characteristics.

EXHIBIT 68–4

Sample of Some Catalysts for Major Downturns, 1990–2010

Source: SG Cross Asset Research.

With regard to noneconomic objectives and constraints, for a variety of reasons the actions of some market participants are at times influenced by somewhat arbitrary factors that are not necessarily related to investment efficiency. For example, the performance of many market participants is measured on a quarterly or annual basis, and as a result they may have limited capacity to "sit on cash." Cash inflows into the bond markets were robust in 2010, and even while many portfolio managers did not see particularly attractive value, they did not have the option of holding high cash balances. In essence, some investors had to buy. But in our experience, valuations supported by "reluctant participants" can be susceptible should volatility or uncertainty edge higher. These investors can look to re-deploy capital to their respective comfort zones quickly.

The factor detailed above goes hand in hand with the market's tendency to be lulled by incremental movements, in our view. That is, if one has to put money to work, is investing in a leverage buyout with 4.5 turns of leverage really all that different from one with 4 turns? Are 5 turns really all that different from 4.5 turns? The problem is that over time the investment community can find itself a long, long way from shore, so to speak. Is 8.5 turns really all that different from 8 turns? No, but it is *very* different from 4 turns. Lastly, the financing of assets is not necessarily done on a matched-maturity basis. If funding becomes more difficult, forced selling can very well ensue and snowball out of control. Mismatched funding can take many paths to influence valuations (hedge fund withdrawals and heightened collateral requirements are two examples).

These characteristics were well exhibited in the housing market crisis that began in 2007. With regard to leverage, Exhibit 68–5 shows that the amount of lower-quality mortgage supply that was originated from 2001 to 2007 grew gradually, but that over time growth became extreme relative to the original starting point. In 2001 and 2002, the supply of Alternative-A loans (Alt-A)—viewed in terms of quality as one notch above subprime—was averaging about $2.0 billion per month.

EXHIBIT 68–5

Monthly Alt-A Mortgage Supply, 2001–1007

Source of data: SG Cross Asset Research, Bloomberg.

This number continually edged higher in the following years—on average $4.4 billion in 2003 and $6.1 billion in 2004. This was still manageable, but before long the average monthly supply was $15+ billion.

Leverage can come in many forms. The robust amount of low-quality mortgage bonds issued was not the only source of housing market leverage in the 2000s. If we define leverage as more exposure to a change in "underlying" valuations (home prices, in this example), then the structured product market boosted leverage in the system severely as well.

Consider common structures back then as shown in Exhibit 68–6. Essentially, a pool of lower-quality mortgage loans was used to create an asset-backed security (ABS), and the mezzanine bond was used to create another, more levered bond, an ABS collateralized debt obligation (ABS CDO). And then a slice of mezzanine debt from the ABS CDO was used to create another security, a CDO with CDO collateral, popularly referred to as a CDO-squared or CDO^2, of which the net effect was an even smaller equity base supporting an even larger debt amount.

So where did we end up? To put the resulting leverage into perspective, in some cases in order to wipe out the entire CDO-squared—all the way through the triple-A tranche—the default rate would only have to hit a 13.4% pace (assuming a 50% recovery and significant overcollateralization). Note that the percentage of seriously delinquent[1] subprime loans as of the third quarter of 2010 according to Bloomberg was 27.7%, more than double the amount needed to impact the triple-A tranches. And at the same time, the number of "reluctant market participants" may have been rising as well—by many metrics valuations were quite full—which may have left prices in the mortgage market particularly susceptible to any rise in volatility or uncertainty. Exhibit 68–7 shows total

1. "Seriously delinquent" percentage is defined as the non-seasonally adjusted rate of loans that are 90 or more days delinquent or in the process of foreclosure.

EXHIBIT 68–6

Evolution of Leveraged Mortgage-Related Structures

Source: SG Cross Asset Research.

assets in money market funds relative to the total return performance of a broad portfolio of mortgage bonds. When volatility edged higher, investors increasingly looked to "park" in cash, and valuations of mortgage bonds had little support and declined soon after.

EXHIBIT 68–7

Total Assets in Money Market Funds versus the CBOE Volatility Index (VIX) and a Portfolio of Mortgage Bonds

Source of data: SG Cross Asset Research, Bloomberg.

Note: As of 4Q 10, returns are last four-quarter rolling average.

The key takeaway here is that there has been an increased focus on tail events, in part because they appear to arise more frequently than expected. We believe that to a large extent this is a function of the following three factors:

1. Market participants' actions may be influenced by factors not necessarily related to investment efficiency, and can "force" investors to take actions unwillingly. Valuations supported by such "reluctant participants" can be susceptible to any increase in volatility or uncertainty.
2. Investors have a tendency to move incrementally, and over time the risk profile of a particular asset class or market segment can increase dramatically and without being noticed.
3. Financing can often be mismatched relative to the assets being supported.

As such, we believe that it is important for investors to always be mindful of the potential for an unexpected drop in valuations as well as ways to protect against possible declines.

OVERVIEW OF SELECT TAIL RISKS

History suggests there may be an innumerable number of tail risk possibilities. Tulip mania? South Sea? Silver? Internet? Housing? It is very difficult to identify bubbles, much less predict when one may burst. However, this does not mean that potential bubbles cannot be effectively hedged, in our opinion.

The goal of this chapter is to provide a framework for hedging tail risk, and in this regard we model three specific risks to be hedged:

1. A severe stock market downturn
2. A sovereign credit event
3. An economic downturn

Below we provide an overview of these tail events.

Stock Market Downturn

Many investors, whether they are equity market investors or not, are cognizant of the performance of the stock market. Because of the depth and breadth of the investor base in this space and the relative liquidity of the stock market, many believe that the equities are an important barometer of risk appetites across all markets. If valuations in the broader stock market encounter pressure, then valuations may well be pressured in other markets as well.

Meaningful declines in the stock market (as gauged by the S&P 500) are not all that infrequent. Over the 25 years from 1985 to 2010 and based on monthly data, for example, the S&P 500 has experienced two-standard deviation declines 12 times and three-standard deviation declines three times (Exhibit 68–8).

EXHIBIT 68–8

Standard Deviation Movements in the S&P 500, 1985–2010

Source of data: SG Cross Asset Research, Bloomberg.

Note: As of December 31, 2010. Monthly change since 1985.

Note that we define an equity market downturn as a risk for fixed income investors in part due to the high correlation between stocks and select segments of the fixed income market, as shown, for example, in Exhibit 68–9. In addition, bond investors, and for that matter investors in general, tend to view both opportunities and risks in a cross market context far more today than in years past.

The key point here is that hedging potential equity market tail events can be important for investors in virtually all asset classes.

EXHIBIT 68–9

EXHIBIT 68–10

Spread Levels in the High-Yield Market and the Spillover Impact the S&P 500

Source of data: SG Cross Asset Research, Bloomberg.

Note: As of January 31, 2011 for SPX, 3Q 10 for corporate profits. Corporate profits include inventory valuation adjustments and capital consumption adjustments, SAAR.

In addition, the equity market tends to be correlated with (or even lead) various economic metrics. For example, in Exhibit 68–10 we overlay historical S&P 500 index levels with corporate profits and we see two very similar trends. As such, one could expect a decline in the equity valuations at times of or in periods leading up to economic downturns, and a softer economic backdrop could very well have implications for other markets.

Sovereign Credit Risk

Public sector fiscal imbalances within many developed countries have increased since the financial crisis in 2008. Some worry that the problem could once again become a market focal point and weigh on valuations.

To illustrate the magnitude of the problem, Exhibit 68–11 shows how drastically the gross debt outstanding for the U.S. and Portugal have risen since 2007. It is worth noting that many public sector entities fit a similar profile. Moreover, history suggests that any public sector credit event could have a meaningful spillover effect on valuations elsewhere. For example, when sovereign fears spiked in the spring of 2010, spread levels for many European financials jumped as investors became worried that their sovereign exposure would require meaningful asset writedowns. Even more distant markets, such as the U.S. high-yield market and the S&P 500, were pressured considerably, as can be seen in Exhibit 68–12.

Economic Downturn

Most asset classes are, at least to some extent, influenced by the broad economic backdrop. For example, one key metric of the economic environment is consumer

EXHIBIT 68–11

Portugal and the U.S. Gross Debt Levels

Source of data: SG Cross Asset Research, Bloomberg, IGCP.

Note: Gross debt level.

confidence, and Exhibit 68–13 shows that there is a fairly high correlation between this economic metric and equity market performance.

But there are many different components of the overall economic background and as a result, hedging an unexpected "downturn" can be challenging. For example, Exhibit 68–14 shows retail sales (ex auto) and corporate profits—two very important components of the broader economy with the potential to significantly influence corporate valuations—have done very different things in

EXHIBIT 68–12

Percent Change in Levels of iTraxx SovX WE, iTraxx Subordinated Financials, and S&P 500, April–July 2010

2009 and 2010. Specifically, during the March 2009 to September 2010 period retail sales growth remained essentially flat, while corporate profits growth was up 44%. Is the economic backdrop good or bad?

The key takeaway is that hedging economic tail risk can be important, but can also be very challenging for a variety of reasons. These include the number of different economic metrics as well as the sensitivity of various asset valuations to these economic subcomponents.

GENERIC CHALLENGES FACING HEDGERS

As noted earlier, there is no perfect hedge. Before attempting to craft an "efficient" hedge for the three tail risks identified in the previous section, we must first discuss the following four challenges that one often faces.

1. The correlation between the portfolio being protected and the hedge vehicle
2. The cost of hedging
3. The potential for slippage
4. The reliance on historical relationships because these relationships can be transitory over time

Correlation

The first challenge that we focus on is correlation, or the chance that the portfolio being hedged and the hedging vehicle itself do not move in the same direction and/or by the same magnitude as expected. Said differently, imagine purchasing an insurance policy to protect against some event, but the payment received when (and if) the event actually occurred was meaningfully different than the actual loss incurred.

To better put this risk into perspective, we consider how specific hedging vehicles have performed historically relative to equity market selloffs (we acknowledge the narrow definition of risk). Exhibit 68–16 examines price changes for the S&P 500 and the Russell 2000 stock indexes from 1980 to 2010 relative to a variety of hedging tools, such as the 10-year Treasury and spot gold. Again, the expectation is that a stock market downturn could have a meaningful spillover impact on certain segments of the fixed income markets.

The observations in Exhibit 68–15 represent periods in which either the S&P 500 or Russell 2000 valuations (or both) declined by 20% or more. Movements of the various hedging tools presented in this exhibit are considered to be at least partially successful if their values changed by 10% or more (and move in the right direction).

This study provides three noteworthy points, in our view:

- Of the 13 times that the stock market declined 20% or more from 1980 to 2010, we see that there are many instances in which various hedging tools did not even move in the "right" direction. For example, while gold can be a beneficiary of a "flight-to-quality" bid during times of turmoil, it nonetheless would not have been an efficient hedge against a decline in equity prices. Spot gold experienced only three observations of "material" movement in the correct direction. And the changes in the value of the dollar was essentially a coin flip during times of significant negative changes in equity valuations—up 46% of the time, down 54%.

EXHIBIT 68–15

Performance of Various Hedging Vehicles, 1980–2010

- Even if the direction of movements between a portfolio being hedged and the hedge itself is highly connected, differences in the magnitude of movements can limit effectiveness as well. For example, Treasuries tend to benefit from a flight-to-quality during periods of severe stress; Exhibit 68–15 shows that the 10-year Treasury moved in the "right" direction 77% of the time. That said, the rise in price of the 10-year seemed fairly modest in comparison to the fall in stock market valuations (e.g., on average the 10-year Treasury price rose 4% versus a decline in the S&P 500 of 21%). One may have to buy an awful lot of Treasuries to hedge, which can present new problems.
- Solely in the context of correlation, we find the VIX and the CDX.IG indexes to be efficient. In terms of consistency, both vehicles moved in the "right" direction each time the S&P 500 and/or the Russell indexes experienced declines of 20% or more, and in terms of magnitude, on average the VIX and the CDX.IG hedges were "in-the-money" by 113% and 84%, respectively.

What Makes the VIX and CDX.IG Indexes Special?

The VIX and the CDX.IG indexes may have many special features, but two that really stand out are the tendency of these vehicles to gap, and for such gaps to be in the "right" direction (i.e., asymmetric payoff profile). With regard to the tendency to gap, we examined how many times the value of the S&P 500 (for reference), VIX, and CDX.IG indexes rose or fell by more than 25% of their respective one-year rolling averages, as shown in Exhibits 68–16 through 68–18. By this

EXHIBIT 68–16

EXHIBIT 68–17

VIX Observations That Are More Than 25% from One-Year Rolling Average from January 1997 to February 2010

Source: SG Cross Asset Research.

Note: As of February 10, 2011.

metric, we see that extreme observations for the S&P 500 are fairly infrequent (4%), particularly when compared to the VIX (28%) or CDX.IG (43%). Note that we have a longer time series for the S&P 500 and the VIX than for CDX.IG.

With regard to asymmetry, we looked at the percent changes for the VIX index and CDX.IG spread over two-week holding periods. We focused on only those observations that moved by 15% or more (see Exhibit 68–19). For the VIX index we find that the number of times since 1997 that the level increased by 15% or more in a two-week period significantly outnumbers the number of times the level declined by 15% or more (459 versus 337, respectively). We find a similar

EXHIBIT 68–18

trend for CDX.IG (71 times for spread tightening by 15% or more versus 156 times spread widening by 15% or more) using data going back to late 2004.

The key point is that a tendency to exhibit large and asymmetric movements is an important characteristic of any hedging vehicle.

Cost of Hedging

The second key challenge that hedgers may face is cost; that is, it may not matter how closely a hedge vehicle tracks the portfolio that one is protecting or by how much the hedge could move should a tail event occur if the cost is too expensive. Purely in the context of correlation short-tenor, at-the-money S&P 500 puts may be a compelling way to protect against declines in the S&P 500, but when cost is taken into consideration this hedging vehicle can be far less efficient.

To get a better sense of the *relative* cost of various hedging tools, we consider seven typical vehicles, such as S&P 500 puts and call options on the VIX index, in the context of equity market tail risk. In Exhibit 68–20 we present the cost[2] of each of these tools and we see that the range is very, very dramatic. For example, the cost of options can be fairly high (e.g., S&P 500 put), while the cost of others tends to be more modest (e.g., CDX.IG). Some hedges actually pay investors to hedge (e.g., Treasuries). Note that in terms of hedge ratio, we risk-weight each of the tools in Exhibit 68–20.

Slippage

The relationship between the S&P 500 and various hedging vehicles may very well exhibit a high correlation most of the time, and the cost may be fairly low as well. But does this mean that it is an efficient hedge? Not necessarily.

2. We assume a 30-day holding period, and the notional amount of each hedge is weighted so that each exhibits the same risk. We use theoretical (calculated) prices for options.

EXHIBIT 68–20

Cost of Various Hedging Tools

Source of data: SG Cross Asset Research, Bloomberg.
Note: As of January 21, 2011.

Another key factor to consider is the potential for infrequent but meaningful "slippage." To illustrate, suppose that an investor used the high-yield index to protect against a sharp decline in equities. One reason for this decision was the relative cheapness of the hedge. Suppose an investor implemented this hedge on January 2, 2009. Over the following year the S&P 500 rallied about 20%, so ideally the high-yield market would have rallied by the same amount or less. However, it did not. A "unique" event occurred and the high-yield market benefited from a return of liquidity to the marketplace and many issuers were able to refinance their upcoming maturities. As a result, the probability of default for the typical high-yield company tumbled drastically (see Exhibit 68–21) and the total return of the high-yield space was 56% in 2009. As such, our investor's portfolio gains would have been wiped out and she would have actually incurred a loss of 36% (S&P +20% – HY +56% = –36%, assuming a notional hedge ratio; see Exhibit 68–22).

Cost, Correlation, and Slippage in the Real World

In 2007 volatility across the marketplace was edging higher, signs of an economic slowdown were emerging, and investors were more and more worried about a potential housing market bubble, among other concerns. By early 2008 many were increasingly worried about the exposure of select banks and brokers to these and other problems. To protect against these risks some investors looked to buy protection in the CDS market on banks and brokers that they viewed as particularly vulnerable (e.g., Bear Stearns). Suppose that an equity investor purchased five-year protection on Bear Stearns in early 2008.

Turns out, there were (at least) two problems with this hedge. First, Bear Stearns protection was fairly expensive—five-year CDS was trading at about 315 bp in the first trading session of March 2008, relative to approximately 165 bp

EXHIBIT 68–21

U.S. Speculative Grade Default Rates, 1971–2010

Source of data: SG Cross Asset Research, Moody's.
Note: As of January 31, 2011.

for the typical name in the high-grade market. As such, if challenges in the banking system did not magnify purchasing this "insurance" could have weighed on performance somewhat.

The second and more significant problem was slippage relative to the S&P 500. Irrespective of the historical correlation between Bear CDS and the S&P 500, a unique event rendered correlation somewhat meaningless. Again, suppose that an investor purchased Bear Stearns CDS at 315 bp in early March. On March 24, the Federal Reserve deemed Bear Stearns "too big to fail" and took the unusual approach of encouraging JPMorgan to absorb Bear Stearns. A slight exaggeration, but in effect Exhibit 68–23 shows that Bear's default risk instantly became JPMorgan default risk (far lower!), and Bear CDS rallied to 186 bp by end of the day. In effect, the hedge would have ended up costing our investor far more than the amount her S&P 500 position had rallied.

Note: Data in Q1 2008.

Reliance on History

Past performance is not an indicator of future returns, the old saying goes. But history is often used to determine how a potential hedge vehicle is likely to perform relative to a particular portfolio. Unfortunately historical relationships can be transient. To illustrate, in Exhibits 68–24 and 68–25 we present the relationship between the 10-year Treasury and the S&P 500 during two different periods, 1970 to 1979 and 2001 to 2010. Exhibit 68–24 plots these two assets during the 1970s, and we see that the correlation was –19%; based on this data one would certainly not expect the 10-year Treasury to be an effective stock market hedging vehicle.

EXHIBIT 68–24

Correlation of the S&P 500 and 10-Year Treasury, 1970–1979

Source of data: SG Cross Asset Research, Bloomberg.

EXHIBIT 68–25

Correlation of the S&P 500 and 10-Year Treasury, 2001–2010

Source of data: SG Cross Asset Research, Bloomberg.

However, the relationship has not been stable over time, and Exhibit 68–25 shows the correlation between these two markets has increased sharply in the 2001–2010 period. Trend reversals occur and can be very dangerous.

UNFUNDED HEDGES (INSURANCE)

A bond investor utilizing an unfunded hedging strategy is essentially looking to purchase an insurance policy. In this section we consider the effectiveness of various unfunded hedging vehicles in the context of the four challenges introduced in the previous section. We define tail risk as a sharp decline in the S&P 500; as noted earlier, over the 25 years from 1985 to 2010 the S&P 500 has experienced two-standard deviation declines 12 times and three-standard deviation declines three times.

In essence, given that stock and credit market performance can be fairly highly correlated, this bond investor is worried about protecting his portfolio from the spillover impact of an equity market selloff. To illustrate, Exhibit 68-26 shows that that from 1997 to 2010 the high-yield market, for example, has experienced eight declines of two standard deviations or more (compared to eight declines in the S&P 500 during the same period as shown in Exhibit 68–27). During the periods that the S&P 500 had declined by two or more standard deviations, the spread in the high-yield market widened by about 19% on average and there were three overlapping periods between the sharp downturns in the equity space and the high-yield market.

Assessing the Effectiveness of Various Hedging Vehicles

The seven common hedging vehicles that we evaluate are Treasury, Treasury future, HY index, CDX.IG, CDX.HY, SPX put, and VIX call hedges. We find that

EXHIBIT 68–26

Standard Deviation Movements in the High-Yield Debt Market, 1997–2010

Source of data: SG Cross Asset Research, Bloomberg.

Note: As of December 31, 2010. Monthly change.

there is no "perfect" hedge, and a tradeoff is required based on a particular investor's preferences, objectives, and constraints. Note that we consider a fairly wide variety of hedging tools in the section, ranging from cash market instruments to derivatives in both the debt and equity markets, because in practice investors have increasingly looked to have as many "tools in the tool box" when identifying potential hedges for debt market downturns.

Before beginning, there are four calculation details to note. First, the performance of each hedging vehicle is based on a base case expectation. In particular, we assume that the most likely market environment is that the S&P 500 is range-bound (70% chance that returns are stuck in the –2% to +2% range), but

EXHIBIT 68–27

Standard Deviation Movements in the S&P 500, 1997–2010

Source of data: SG Cross Asset Research, Bloomberg.

Note: As of December 31, 2010. Monthly change.

with a meaningful chance (30%) that the S&P 500 falls by up to 15%. Hedge performance is based on these probabilities and magnitudes, and as we will show later alternative scenarios can change results meaningfully.

Second, in terms of the weighting of each hedge vehicle, notional sizes are determined in a risk equivalent context. That is, in dollar terms we calculate the P&L range for a $10 million investment in the Treasury market in each scenario that we evaluate. We then back out notional weightings for the other hedge vehicles to generate the same risk profile (P&L range).

Third, the expected P&L for each hedge is based on their betas relative to the S&P 500 since 2005 (daily observations). We calculate four separate betas for each hedging tool—fairly modest bullish moves in the SPX (gains of less than 7.5%), more extreme bullish moves (SPX gains of 7.5% or more), and we use the same approach to determine betas in bear markets (SPX declines of up to 7.5% and more than 7.5%). Finally, the horizon is 30 days.

We discuss four findings in particular:

1. Dramatic differences in payoff profiles
2. Variation of success
3. Possibility of our base case being wrong
4. Slippage

Payoff Profiles Can Vary Dramatically

In Exhibit 68–28 we present the P&L for the seven hedges. We find that in absolute dollar terms the effectiveness of the various hedges varies dramatically—the range of P&Ls was $40,000 as of January 2011.

EXHIBIT 68–28

P&L for Various Hedge Vehicles in Our Base Case Scenario (70% Chance of Being Range-Bound, 30% Chance of S&P 500 Falling by Up to 15%)

Source: SG Cross Asset Research.

Note: As of January 21, 2011. We assume a 30-day holding period, and the notional amount of each hedge is weighted so that each exhibits the same risk. We use theoretical (calculated) prices for options to calculate the return.

By this measure of effectiveness the Treasury market hedge (long cash or futures) was the best performer, as it earned money in a status quo scenario (coupon clip), but also benefited from a flight-to-quality in more bearish scenarios. Interestingly, the S&P put comes in the sixth place, in part because it is fairly expensive. The cash high-yield cash market came in the last place, in part because it is a fairly expensive hedge and can be driven by factors that can have less of an impact on equities (e.g., defaults).

There Are Many Variation of Success

But this does not mean that Treasuries are the best hedge per se. That is, a P&L of $42,000 may go a long way to offsetting any loss we may incur due to falling equity prices, but remember that the notional exposure required to generate this return is $10 million! In comparison, the put position only requires a notional exposure of $43,000. In the context of return on notional exposure, the put position would outperform dramatically, 33.8% versus 0.4% (Exhibit 68–29).

Some investors may not have any constraints in terms of how much notional exposure they can have to a particular position, or how much balance sheet that they can tie up with any particular trade, etc., but many do face some of these constraints and the best hedge for these market participants may be something less "capital-intensive."[3]

EXHIBIT 68–29

Return on Notional Exposure

Asset	P&L ($k)	Notional ($k)	Return (%)
Trsy	42.4	10,000	**0.4**
T30 Fut	42.3	6,700	**0.6**
HY Index	2.4	3,800	**0.1**
CDX.IG	20.8	8,400	**0.2**
CDX.HY	16.1	2,375	**0.7**
SPX Put	14.6	43.1	**33.8**
VIX Call	22.6	69.3	**32.6**

Source: SG Cross Asset Research.

Note: As of January 21, 2011.

3. We acknowledge that collateral requirements for Treasuries are modest, but we do not explicitly consider the impact of leverage in this analysis.

Possibility of an Incorrect Base Case

Another important consideration is performance should our base case scenario be incorrect. Recall that our base case was that a range-bound market was most likely (70%), but that there was a 30% chance that the S&P declines by up to 15%. How would performance look if the chance of improved valuations was much higher and stocks rallied instead of falling sharply?

In Exhibit 68–30 we present P&L for our various hedges in an environment in which stocks rally by 5%. Perhaps the most important point here is that the susceptibility to an incorrect market call is limited for some vehicles, but not for others. For example, the most that the S&P put can lose is the option premium ($43,000; note that this is different from the option cost shown in the exhibit which reflects the cost for only the one-month holding period). Conversely, the high-yield hedge (cash) loses $64,000, in part due to the coupon paid ($22,000) but also due to a mark-to-market loss of $42,000. Treasury hedges do well in this scenario, primarily because there is no upfront cost for the hedge—a coupon is *earned* with this hedge, not paid.

What about Slippage?

In the context of some risks the Treasury hedge appears to be particularly effective, but the tool can be especially vulnerable to others, such as slippage. That is, the historic relationship between stocks and Treasuries might be fairly strong, but the Treasury market can be far more sensitive to factors such as monetary policy and inflation expectations than the equity market. As a result slippage can be dramatic at some points in time.

EXHIBIT 68–30

P&L for Various Hedge Vehicles in a Moderately Bullish Scenario (S&P 500 up 5%)

Source: SG Cross Asset Research.

Note: As of January 21, 2011. We assume a 30-day holding period, and the notional amount of each hedge is weighted so that each exhibits the same risk. We use theoretical (calculated) prices for options to calculate the return.

EXHIBIT 68–31

S&P 500 versus 30-Year Treasury Price

Source of data: SG Cross Asset Research, Bloomberg.

Note: From January 15, 2009 to June 15, 2009.

To illustrate, suppose that an investor bought a 30-year Treasury position to protect against a potential stock market setback on January 15, 2009. Over the next several months, equities performed well, but Treasuries sold off far more than their beta (versus the S&P 500) would suggest primarily because the bond market began anticipating and pricing in more inflation. As a result, the hedge would have lost 25% over the next few months, which is significantly more than the stock market gain of 9.6% (Exhibit 68–31).

The key takeaway is that unfortunately, there does not seem to be a perfect hedging vehicle to minimize exposure to tail risk. Four key challenges tend to impact the effectiveness of most hedges—cost, correlation, slippage, and reliance on historical relationship. In effect, investors must weigh these challenges (and others) with their own market expectations, objectives, and constraints.

That said, we examined a variety of hedging vehicles in several different scenarios, and found that in the context of these challenges the CDX.IG and the VIX indexes can be particularly effective. Vehicles such as Treasuries can do well in most scenarios, but do have significant slippage risk, and the performance of some options (e.g., short-tenor, at-the-money S&P puts) can be constrained by cost.

FUNDED HEDGES (ALPHA TRADES)

In the previous section we examined unfunded hedges, which in some respects are comparable to the outright purchase of an insurance policy. The cost of the policy is obviously a concern, but not necessarily an investor's primary concern. In this section we introduce funded hedges, or package trades in which some long exposure is used to pay for the cost of insurance. As a result the net hedge cost declines, but there is a tradeoff as other challenges can become more intense and new ones introduced. For example, counterparty risk can be an important consideration when employing a funded hedge strategy.

EXHIBIT 68–32

Nasdaq vs. S&P 500, 1995–2000

Source of data: SG Cross Asset Research, Bloomberg.

The reason why many market participants use funded hedges tends to result from two factors. First is the impossibility of being able to accurately predict the timing of a tail event. In practice, at best one may be able to do is anticipate a higher (lower) probability of an event occurring over a given time frame. Second, the performance of many investors is measured against a benchmark index or relative to the performance of competitors over a fairly short time. As such, if a tail event does not occur fairly quickly, the relative performance of an investor using an *unfunded strategy* will likely be negative, at least by some metrics.

Suppose that back in early 1995 an equity investor that was benchmarked against the S&P 500 on an annual basis was worried about "irrational exuberance." She shorted the segment of the stock market that she believed was most irrational—the NASDAQ. Unfortunately for this investor, while the equity market may very well have been irrational, such irrationality lasted for five more years. By early 2000 the NASDAQ had rallied 500% from early 1995 levels, and this investor would have lagged her benchmark by over 300%, as seen in Exhibit 68–32.

In this section, we evaluate funded hedges in the context of two specific risks (sovereign risk, economic downturn), but before proceeding there are three important points to make:

1. *Focus, focus, focus:* As a rule of thumb, unfunded hedges tend to protect portfolios against a wider variety of events than funded hedges, and this is primarily because funded hedge packages have both long and short elements (as opposed to an unfunded hedge with just short exposure). Essentially, the goal of a funded package is to short an asset that is particularly sensitive to a specific problem, and go long an asset that is fairly immune.
2. *Use scenarios more than history:* In the previous section our analysis of hedge efficiency was to a large extent based on history—if the S&P

500 moves by X amount, then hedge XYZ can be expected to move by Y amount. But funded hedges rely more heavily on scenario analysis than historical relationships. In essence, the goal is to construct a package that provides an asymmetric payoff profile across a wide variety of potential scenarios with a tolerable amount of downside risk. In this regard, more qualitative analysis may be needed.

3. *Additional risk factors introduced:* Funded packages also have more "moving parts" than unfunded packages and as a result additional risks can come into play. For example, counterparty, mark-to-market, and liquidity risks, to name a few, can all be found in abundance in funded hedges.

Again, in this section we provide two examples of funded hedges. We first focus on a sovereign risk hedge, and then a hedging vehicle to protect against an economic downturn. We find that while funded hedges have more "moving parts" and potential risks than unfunded hedges do, these risks can often be managed and results very effective.

Sovereign Fiscal Imbalances

While for many decades the focus of fiscal solvency has been in the emerging markets, sovereign default has become a risk factor in many developed economies as well. Public debt levels have spiked since 2007 (Exhibit 68–33) and some do not believe that all governments have the political wherewithal to solve the challenge.

One lower cost strategy to protect against a potential sovereign credit event is to go long names with little direct risk to public sector fiscal imbalances and

EXHIBIT 68–33

Portugal and the U.S. Gross Debt Levels, 1996–2010

Source of data: SG Cross Asset Research, Bloomberg, IGCP.

Note: Gross debt level.

fairly limited near-term risk in general. The income from this portfolio could be used to pay for short exposure to issuers with significant direct exposure to the sovereign problem and/or other near-term challenges.

Consider the package presented in Exhibit 68–34. The names of the companies and countries in the long and short positions of the package cannot be disclosed, but the levels presented in the exhibit reflect the real life values as of September 2010. The short side of this package is composed of names that had at least some of the following characteristics as of late 2010:

1. A direct link to the weak credit profile of the public sector
2. Meaningful maturities coming due in the near term (total of $295 billion through 2012). Refinancing could be a significant challenge should sovereign fears rise further and market participants begin to worry about a spillover into the banking system.
3. More cyclical names that (as of September 2010) could be particularly vulnerable to an economic slowdown caused by sovereign concerns.

The cost of this portfolio at a time when sovereign fears were particularly intense (mid-September 2010) was 1170 bp, based on one-year CDS (as of September 14, 2010). To overcome this fairly prohibitive cost one could use a one-year first-to-default structure (FTD); FTD packages pay those with short exposure in the event that any one of the names in the structure defaults, but only one. There is no additional payment should two, three, or more names experience a credit event.

The benefit of using this structure is that it costs relatively little to establish a short position. As of mid-September 2010 the cost was approximately 70% of the portfolio's sum-of-spreads (1,170 bp). So an investor only would have to pay 819 bp to short exposure to the basket of vulnerable names (1,170 bp × 70% = 819 bp).

This short position can be funded with long exposure to select names that appear to have little near-term default risk. Part of the reason is simply because the names in the long position in Exhibit 68–34 have little or no debt coming due in the period 2010–2012. Three of the five names have no upcoming maturities through 2012, and in aggregate only about $240 million will mature during this period.

In addition, the average implied default rate is far lower for the long positions than for the short positions (0.7% versus 3.0% average implied default rates, assuming 40% recovery for corporates and 70% recovery for sovereign names as of September 14, 2010). The market did not perceive all that much near-term risk for the long candidates (again, as of September 2010).

The key point is that short exposures appear to be more vulnerable to spread-widening catalysts, and the position is positive carry (151 bp, as of September 2010).

Potential Risks

This trade package can benefit in the event of a sovereign credit event, but it does have risks that should be considered. For example, an FTD is an over-the-counter derivative product and is subject to non-standard prices that a bank or other dealer may provide upon unwinding, and as such the package is vulnerable to illiquidity. This risk is tempered, however, because of the fairly short tenor of the package—worst case, an investor can hold to maturity (one-year).

The aggregate delta mismatch is also a risk, but there are several factors that help to offset it. Specifically, the short tenor of the package limits the impact in absolute dollar terms, and the range-bound spread environment that the market was in can help to limit the severity of mismatch as well. Exhibit 68–35 shows that the high-grade market had been trading in a very tight range from mid to late 2010. If spreads do not move, delta mismatches do not matter.

And the notional mismatch—$50 million versus $10 million—is also a potential challenge. But let's take a step back from the FTD package itself and consider the riskiness of the underlying constituents. From a credit perspective, which is more risky—a $100 million Treasury position or $10 million exposure to First Data (rated B3/B/B) paper? Large exposure to a low probability event or small exposure to a higher probability event? In a risk-adjusted context, one could argue that the Treasury position is less risky.

Marking-to-Market: The FTD Hedge

While there are more moving parts with these relatively complicated packages, they can be very efficient hedging vehicles. For example, we marked-to-market the FTD trade package three months after it was initiated (i.e., December 15, 2010). Exhibit 68–36 shows that this package was deeply in-the-money, the long

portion of the portfolio being 429 bp tighter and the short portion being 109 wider. In dollar terms this translates into a gain of $2.3 million, which could go a long way to offsetting any sovereign-induced decline in a portfolio.

Economic Downturn

One of the biggest risks that portfolio managers in virtually all asset classes face is exposure to severe economic downturn. That said, we believe that "cheap" and effective economic downturn hedges can be found. In this section we present an example of a positive carry package with an asymmetric payoff profile that existed in the credit space when heading into the 2007 recession. The favorable payoff profile resulted in large part from a unique combination of sector specific characteristics and the shape of select CDS curves.

With regard to sector characteristics, in the credit market all sectors tend to suffer heading into and during the early portion of recessions, but the extent of suffering can vary sharply. To illustrate, Exhibit 68–37 highlights the total returns of cyclical and noncyclical sectors in the high-yield market in 2008. On average the cyclical sectors generated a total return of –32% in 2008, while the non-cyclicals were far more resilient (–16%). So from this perspective shorting select cyclical sectors may have been the most effective trade.

But which one should be shorted? For unique reasons at any given point in time some sectors may be even more vulnerable than others heading into an

EXHIBIT 68–37

Total Returns of Cyclical and Non-Cyclical Sectors in the High-Yield Market, 2008

Source of data: SG Cross Asset Research, Bloomberg.

economic downturn. As noted above, there were numerous challenges in the economic backdrop back in early 2007, but many of the challenges centered around a potential bubble in the housing market. So ideally, back in 2008 shorting cyclical companies with exposure to the housing market, such as the homebuilding space, might have been a good hedge.

But what about the cost? Turns out, the cost of shorting the typical homebuilder heading into the last recession was not prohibitive either. Despite appearing to be more vulnerable to a slowdown, on average spreads in the homebuilder space were about the same as those in most other sectors. Exhibit 68–38 shows that the typical homebuilder (292 bp) was essentially trading at the same level as the typical cyclical (298 bp) and the typical non-cyclical (273 bp).

The key point is that homebuilders appeared to be particularly vulnerable to an economic downturn yet spread levels were very much in-line with the typical names in the market. Affordability is a good starting point for an effective hedge.

But the challenge is to craft a trade package that does not cost much, if anything, and has an asymmetric payoff profile. In this regard we can take advantage of the fact that many homebuilders had very steep credit curves prior to the 2008 recession. For example, KB Homes, a benchmark issuer in the homebuilding space, had a three-year/five-year spread slope of 111 bp heading into the 2008 recession (Exhibit 68–39), relative to about 100 bp for the typical high-yield name.

The steep curve enabled a potential investor to duration-weight a curve flattener and still earn positive carry. In effect, one could buy (go short) $15 million

EXHIBIT 68–38

Spreads of Cyclical and Non-Cyclical Sectors in the High-Yield Market, 2007

Source of data: SG Cross Asset Research, Bloomberg.

Note: As of January 2, 2007.

EXHIBIT 68–39

Source of data: SG Cross Asset Research, Markit.

of three-year KBH protection and sell (go long) $10 million protection in the five-year tenor, and be duration-neutral and still earn 49 bp in carry (Exhibit 68–40). The curve flattener, when combined with the potential susceptibility of this name to an economic downturn and its fairly tight spread levels, resulted in a package with an asymmetric payoff profile.

Consider the following four scenarios:

1. *Status quo:* Again, the steep slope of the KBH credit curve enabled a potential hedger to implement a duration-weighted 3s/5s curve flattener (hedge ratio of about 1.5×) and still earn 49 bp (Exhibit 68–40). And such, results are modestly favorable in a status quo scenario, particularly in a ROE context (as the position requires little collateral).
2. *Coin flip:* If the economy did not slow down and valuations simply "bounce around" the position should be fairly immune because it is duration matched.
3. *Bullish:* The package would likely be susceptible if an economic downturn did not occur and spreads tightened, but this risk is mitigated in part by positive carry and already tight spread levels. How much tighter can the front-end get?
4. *Bearish:* As a rule of thumb, credit curves typically flatten sharply when default risk increases, and default risk rises when the economy slows as shown in Exhibits 68-41 and 68-42. This package is well positioned to benefit, not only due to the disproportionate change in CDS spreads (short-tenor spreads under more pressure than longer-tenor ones), but also because of the disproportionate amount of protection bought and sold ($15 million versus $10 million).

EXHIBIT 68–40

KBH 3Y/5Y Curve Flattener

Action	Curve	Notional Amt	Duration	Spread
BUY	3-yr	$15 mm	2.9	111bp
SELL	5-yr	$10 mm	4.4	215bp
Carry				**+49bp**
ROE				**19%**

Source of data: SG Cross Asset Research, Bloomberg, Markit.

Note: As of March 15, 2007. We assume a lower risk profile fund and calculate the initial margin to be $250k, based on the gross notional amount.

We price the KBH trade package after a one-year holding period (as of March 14, 2008). Exhibit 68–43 shows that the KBH curve inverted sharply—three-year protection widened 407 bp, while five-year protection increased 251 bp—and Exhibit 68–44 shows that this package generated a positive P&L of $0.3 million (ROE of 122%).

The key takeaway is that as a rule of thumb funded hedges have more "moving parts" and potential risks than do unfunded hedges. That said, the risks can often be managed, in our experience. In this section we examined using funded hedges to manage two specific risks—public sector fiscal imbalances and an economic downturn—and found positive carry hedges that in theory offered an asymmetric

payoff profile. We then marked-to-market these packages, and found that theory was consistent with reality.

Trade-Specific Risks

As discussed, most hedges face, at least to some extent, four generic challenges. In addition, many packages also have trade-specific challenges/risks as well. For example, if an investor purchases protection via the CDX.IG index he/she may be exposed to mark-to-market risk. Investors that mark portfolios to market are subject to potentially large movements in P&L that may cause a position to trigger a stop/loss. As we discussed in an earlier section, in 2007 market volatility was

increasing and investors sought to buy protection in the CDS market on banks and brokers that they viewed as particularly vulnerable. But ensuing spread widening was certainly not one directional, and some investors could have been forced out of positions (stop loss) even if they ultimately finished in-the-money.

The sovereign hedge described previously most certainly has liquidity risk (i.e., bid/ask spread could widen sharply if the package holder tried to unwind the position) as well as counterparty risk. With regard to liquidity risk, an investor seeking to capture the P&L of a particular trade that is in-the-money should consider the sizing and appropriate execution costs upon entering and exiting a position *in a normal versus a stressed scenario*. As a subset of liquidity risk, positions that are purchased on margin are particularly susceptible, as changes in margin or collateral requirements during stressful market periods can be dramatic.

The important point is that there are a large number of trade-specific risks for which one must account. We do not attempt to identify or analyze all potential risks within various hedges, but we do walk through one specific example in this section. In particular, we calculate a potential cost of counterparty risk for the Bear Stearns hedge described earlier.

The Cost of Counterparty Risk

It may be possible to control counterparty risk via regular reviews of trading partners, collateral requirements, etc., but however controlled it can be, it probably cannot be completely eliminated. Earlier we walked through an example in which an investor bought CDS protection on Bear Stearns as a hedge. Using the same example, assume again that the investor bought five-year CDS protection on Bear in early March 2008 at 315 bp, but add the wrinkle that the position was

purchased from Lehman. The key question is whether or not Lehman will be around to provide compensation should Bear default. Note that Lehman CDS was trading at 228 bp at the time.

Counterparty risk is to a large extent a function of two factors:

1. The joint probability of default (i.e., Bear and Lehman both experience a default);
2. The size of a loss in the event of a default, which depends on recoveries for both Bear and Lehman; that is, if Bear defaults our investor would be owed a certain amount by Lehman, but if Lehman also defaults this claim probably would not be paid in full.

We rely on the following equation to calculate how much this counterparty risk costs in terms of basis points:

$$\begin{aligned}&\text{Counterparty risk}\\&= \text{Joint default probability} \times [100 \times (1 - \text{Recovery}_{\text{BSC}})\\&\times (1 - \text{Recovery}_{\text{LEH}}]/\text{Duration}_{\text{BSC}}\end{aligned}$$

If we assume recovery rates of 40% for both Bear and Lehman, and that five-year CDS spread levels are entirely compensation for credit risk, the implied default rate is 23.1% for Bear Stearns and 17.3% for Lehman. As such, the extra compensation that investors should receive for counterparty risk is about 36 bp as shown below:

$$\begin{aligned}\text{Joint default probability} &= \text{Default probability}_{\text{BSC}} \times \text{Defaulty probability}_{\text{LEH}}\\&= 23.1\% \times 17.3\% = 4.0\%\\\text{Counterparty cost} &= 4.0\ \% \times [100 \times (1 - 40\%) \times (1 - 40\%)]/\ 4.0 = 36\text{ bp}\end{aligned}$$

The key point is that the cost of Bear protection was probably higher than the nominal spread of 315 bp. By some metrics the cost of counterparty risk alone is 36 bp, pushing the true cost to 351 bp (315 bp + 36 bp).

KEY POINTS

- Tail events tend to occur more often than one might expect, in large part because (1) the actions of investors can be influenced by factors that are not necessarily related to investment efficiency, (2) market participants tend to move incrementally and over time risk profiles can increase dramatically, and (3) the financing of risk assets and/or operations tends to be transitory and the lack of stable access to financing can cause any modest change in valuations to snowball.
- If and when an investor decides to hedge, it is important to understand exactly what is to be hedged. One type of tail event (e.g., sovereign default) could require a very different type of hedge than another (e.g., BP oil spill).

- There is no perfect hedge. Four challenges that should be considered for most hedge vehicles are (1) correlation (i.e., the likelihood that a hedged asset and the hedging vehicle do not move in the same direction and magnitude), (2) cost, (3) potential slippage that can be induced by the sensitivity of the hedge or the hedged asset to a unique development, and (4) the reliance on history, since the relationship can be transitory over time. In addition, there can be a number of trade-specific risks that are important to consider as well (e.g., counterparty risk, liquidity, etc.). In effect, investors must weigh these challenges with their own market expectations, objectives, and constraints.
- Unfunded hedges are defined as those for which an investor is willing to dedicate a certain amount of capital to protect the portfolio. In some respects, unfunded strategies are comparable to insurance policies. The cost of the policy is obviously a concern, but it is not necessarily an investor's primary concern.
- An evaluation of seven unfunded hedges in the setting of declining equity prices finds that while there is no perfect hedge for all investors, various VIX and CDX.IG strategies can be efficient in a fairly wide range of scenarios. A tendency to exhibit large and asymmetric movements is an important characteristic of any hedging vehicle.
- Funded hedges are defined as packages in which some long exposure is used to pay for the cost of insurance. As a result, the net hedge cost declines, but there is a tradeoff as other challenges can become more intense and new ones introduced.
- Funded hedges typically become more popular when the timing of any potential negative catalyst is difficult to ascertain and when performance of investors is measured over a fairly short period of time. We find that while funded hedges have more "moving parts" and potential risks than unfunded hedges do, these risks can often be managed and hedge results can be effective.

Performance measurement and attribution is an important function of portfolio management. It helps bring clarity to the sources of portfolio risk and performance, quantify the contributions of individual decision-makers and identify structural issues. Performance attribution algorithms typically follow either a sector-based allocation or a factor-based allocation methodology, but neither is sufficient to cope with the complexity of modern portfolio management. In this chapter, we first discuss the principles of performance attribution. We review the sector-based and factor-based attribution frameworks then describe a hybrid attribution model[1] that blends the two and has the flexibility to adapt to the particular

The authors would like to thank Lev Dynkin for introducing us to the concept of performance attribution, Jay Hyman for many insightful ideas over the years and Attakrtit Asvanunt who was instrumental in the development of many concepts in this chapter.

management structure of most portfolios. The chapter finishes with the application of performance attribution, both as a portfolio management tool and a data quality tool. Where possible, we introduce the best practices for performance measurement and discuss practical considerations in real-world applications. Throughout the chapter, we utilize examples produced by the Barclays Capital Hybrid Performance Attribution (HPA) model[2] as implemented in POINT, the Barclays Capital portfolio analytics and modeling platform.[3]

PRINCIPLES OF PERFORMANCE ATTRIBUTION

Managing a global diversified portfolio of financial assets is a complex task that requires adopting views in different markets and implementing them with regular trading activities. Expressing and implementing views in a variety of markets that interact with each other in complex ways, makes it very difficult to quantify the contribution of each decision-maker to the performance of the portfolio. Performance attribution is a mathematical framework that attempts to split the total outperformance of a portfolio versus a benchmark into the contributions of individual decisions and actions.

Complex portfolios are typically managed by breaking down the investment process into a sequence of decisions made by different managers, each of whom specializes in a specific market or type of security. Traditionally, this process follows product and sector lines. Risk-factor-based portfolio management became popular with the advent of modern portfolio risk management and the realization that certain risks are common for multiple asset classes. Foreign exchange (FX) and interest rates are examples of risks that are now commonly being managed separately for the entire portfolio while product/sector experts focus on managing excess returns.

The total outperformance of a portfolio depends on the combined outcome of the decisions of all portfolio agents, as well as the market performance. Often, the effects of different agents' decisions depend on each other in a way that makes it difficult to disentangle them. A successful performance attribution algorithm will do so in a way that satisfies three important requirements:

- *Additivity*: The contribution of two or more agents combined is equal to the sum of the contributions from those agents.
- *Completeness*: The sum of all outperformance contributions is equal to the total portfolio outperformance.
- *Fairness*: The allocation of outperformance to different interacting agents is performed in a way that is perceived to be fair by all agents.

2. For details of the model see Anthony Lazanas, Chris Sturhahn, and Pamela Zhong, *The Barclays Capital Hybrid Performance Attribution (HPA) Model* (Barclays Capital Publications, October 2010).
3. Both Hybrid Performance Attribution and POINT are registered trademarks of Barclays Capital.

These requirements are important because performance attribution is often used to measure the skill level and determine the compensation of portfolio managers. The fair decomposition of portfolio outperformance must take into account the management structure of the portfolio. In addition, a good performance attribution model or system needs to successfully address multi-period compounding and have sufficient flexibility in order to meet the demands of modern portfolio management.

Multi-Period Attribution and Compounding

Generally speaking, a performance attribution model measures the exposure of a portfolio to various markets at the beginning of a period and then explains the contribution of each market to the performance of the portfolio over the period as the product of its exposure to the market times the market move. Since actively managed portfolios dynamically adjust exposures to various markets frequently, such performance attribution over a period of time will not capture the effect of active portfolio management.

For example, consider a portfolio that begins the attribution period with no exposure to a particular sector. During the period the sector rallied and in response the manager allocated positive exposure to the sector. Subsequently the sector lost all of its gains and ended the period flat. Since the portfolio had no exposure when the sector rallied but positive exposure when the sector retreated, the portfolio realizes losses over the period. An attribution system that looks at exposure at the beginning of the period (zero) and the return of the sector over the period (also zero) will not be able to explain the realized losses. A system using average exposure over the period will also fail to explain the losses since the return of the sector is zero over the period. On the other hand, a system that splits the attribution exercise in two (or more) subperiods and then combines the results of the subperiods to explain the total portfolio performance over the entire period will be able to identify the intra period exposure adjustment as the reason for the portfolio losses.

The length of the subperiods that an attribution system uses to explain performance over longer periods determines the frequency of the attribution system. Linking the returns of subperiods is called compounding. Timing affects investment performance, especially when intermediate cash flows occur. Since cash flows impact portfolio market value, the fundamental question is whether sub-period returns should be compounded without regard to the portfolio size during each subperiod (time-weighted compounding) or whether subperiod returns should be weighted by the portfolio market value in each period (money-weighted compounding). For example, consider a portfolio with a seed investment of $1,000,000 that earns a rate of return of 100% doubling its value for the first half of the year. Because of its success, the portfolio attracts additional investments of $100,000,000 and its market value becomes $102,000,000. Unfortunately, in the second half of the year it has losses of 10% ending the year with a value of $91,800,000. What is the annual return of the portfolio? Assuming the inflow

are immediately shown in the quality of the results. An example of this is discussed later in the chapter.

Flexibility

A practical performance attribution system must reflect the decisions that a portfolio manager makes during the normal course of the investment process. With a wide diversity among portfolio managers also comes a wide diversity of styles that are often mutually exclusive. No single specification of a performance attribution can describe all managers' preferences. In order to be useful, the model must also satisfy the following requirements:

- Measure the risk factors corresponding to the portfolio managers' decisions
- Independently measure the contributions of each factor in the portfolio management process
- Closely follow the published returns of the fund, and its benchmark
- Be available in a timely manner
- Have sufficient adaptability to explain both short and long time periods

In short, it must be useful to the portfolio manager in explaining and refining her decisions, quantifying the effects of the investment process.

MATHEMATICS OF PERFORMANCE ATTRIBUTION

Performance attribution algorithms typically follow either a sector-based allocation or a factor-based allocation methodology. Both methods follow the same framework which expresses the total outperformance of the portfolio over a benchmark $R^P - R^B$ as the sum of several components. The contribution of each component is determined by a portfolio manager's decision to allocate a different exposure than the benchmark to a particular market or factor, and the performance of the market or the factor itself. In this section, we first discuss sector-based and factor-based attribution under this simple framework, and then introduce a hybrid model that blends the two and has the flexibility to support virtually all types of portfolios and portfolio management styles. We will develop the mathematical framework of performance attribution assuming a generic set of sectors and factors. In Chapters 70 and 71 we will see the application of this framework in the performance attribution of fixed income portfolios.

Sector-Based Attribution

In its simplest form, portfolio management versus a benchmark is modeled as a two-step process that consists of market weight allocation to various sectors and

occurred in the middle of the year, money-weighted rate of return estimates the annual return by solving for the internal rate of return:

$$1,000,000 \times (1+r) + 100,000,000 \times (1+r)^{0.5} = 91,800,000 \Rightarrow r = -17.24\%$$

Time-weighted rate of return ignores the portfolio size and reports an annual return of:

$$r = (1+100\%) \times (1-10\%) - 1 = 80\%$$

Given the dramatic differences between the two methods when portfolio flows are significant relative to its current size, the choice between the two methods is an important decision. Whether the timing of cash flows should be reflected in return measures depends on whether the portfolio manager is responsible for the timing of the cash flows. If she is responsible, then money-weighted method should be used. In the case of mutual fund or pension fund managers who have no direct control of cash contributions and withdrawals, the time-weighted method is more appropriate. In the following three chapters we assume the time-weighted methodology.

Once the method for compounding returns is decided, the question of splitting multi-period returns into components (i.e., multi-period performance attribution) must be addressed. The difficulty arises from the fact that compounding is a nonlinear function and introduces interaction terms that must be allocated between different return components. For example, consider that the portfolio return is attributable to two components which both contribute 10% of return over two periods. The return of the first component is realized during the first period, and the return of the second component is realized over the second period. Time-weighted compounding will report total portfolio return of (1+10%) × (1+10%) – 1 = 21%. Each component contributes 10%, leaving 1% of total return that can be claimed by either component. A multi-period attribution system must adopt both return and outperformance compounding algorithms that retain the principles of additivity, completeness and fairness. Such algorithms are discussed in more detail in Chapter 71.

It is important that the frequency of the attribution system match the frequency of portfolio management decisions. If the attribution frequency is too low, as in the example above, part of the portfolio performance may remain unexplained. Conversely, if the attribution frequency is too high, the attribution model may attribute outperformance to portfolio management erroneously. Many fixed income portfolios are managed on a daily basis, especially with respect to their interest-rate exposures; therefore daily-frequency attribution models are commonly used for fixed income portfolios. Daily compounding generates the requirement for high-quality daily prices and analytics for all securities in a portfolio and its benchmark. Sophisticated attribution systems can be used as a magnifying glass for data quality. Any problems with the data

security selection within each sector. The classical performance attribution methodology is often referred as "Brinson model."[4] Portfolio return is the market value-weighted (w_s) sum of the individual sector returns, R_s:

$$R^P = \sum_s w_s^P R_s^P$$

Similarly, benchmark return is the weighted sum of benchmark sector returns:

$$R^B = \sum_s w_s^B R_s^B$$

This representation allows us to identify two key drivers of the total outperformance $R^P - R^B$: the differences in the sector allocations, w_s, and the differences in the returns, R_s earned within each sector. The outperformance achieved by reweighting the sectors is called "Asset Allocation," and the outperformance due to the intrasector return differences is called "Security Selection." To make the decomposition of the total outperformance complete, we need to add a third term, the "Interaction" effect, the joint effect of asset allocation and security selection.

Asset Allocation $$\sum_s \left(w_s^P - w_s^B\right) \cdot R_s^B \tag{69–1}$$

Security Selection $$\sum_s w_s^B \cdot \left(R_s^P - R_s^B\right) \tag{69–2}$$

Interaction $$\sum_s \left(w_s^P - w_s^B\right) \cdot \left(R_s^P - R_s^B\right) \tag{69–3}$$

Interaction terms arise every time two factors contribute to outperformance through a non-additive function such as the product. Interaction terms are philosophically undesirable, since the stated goal of performance attribution is to credit agents separately for their contribution. Thus, we attempt to merge interaction terms into other outperformance components that can be uniquely attributed to a single agent. The criteria for consolidation are usually dictated by the order in which decisions are made, or the relative size of the interaction term.

The standard assumption is that asset allocation precedes security selection (i.e., the portfolio is managed in a top-down fashion), so it is common to fold the interaction term into the latter:

Asset Allocation $$\sum_s \left(w_s^P - w_s^B\right) \cdot R_s^B \tag{69–4}$$

Security Selection $$\sum_s w_s^P \cdot \left(R_s^P - R_s^B\right) \tag{69–5}$$

4. Gary L. Brinson and Nimrod Fachler, "Measuring Non-U.S. Equity Portfolio Performance," *Journal of Portfolio Management*, 11, 3 (1985), pp. 73–76 and Gary L. Brinson Randolph. Hood and Gilbert Beebower "Determinants of Portfolio Performance," *Financial Analysis Journal*, 42, 4 4 (1986), pp. 39–44.

If, on the other hand, the expected returns of sectors in the portfolio are different than those in the benchmark (for example, because of manager skill or leverage), then it might be more appropriate to fold the interaction term into asset allocation instead. As a result, asset allocation would be given by $\sum_s \left(w_s^P - w_s^B\right) \cdot R_s^P$ and security selection would be given by $\sum_s w_s^B \cdot \left(R_s^P - R_s^B\right)$. It is easy to see that in both cases, the outperformance breakdown is complete; i.e., the sum of the two components is equal to the total outperformance.

The above formulas would assign positive contribution to asset allocation outperformance to any overweighted sector with positive benchmark sector return. Thus, if all sectors have positive benchmark returns, overweighting the sector with the worst return would still be considered a good decision. This is intuitively wrong in most portfolios, as the weight allocated to such sector would be better used in sectors with higher returns. Therefore, instead of using the absolute benchmark sector return in the above asset allocation formula, one can use the sector return relative to the benchmark return (which represents the weighted average return of all benchmark sectors):

$$\text{Asset Allocation} \qquad \sum_s \left(w_s^P - w_s^B\right) \cdot \left(R_s^B - R^B\right) \tag{69–6}$$

$$\text{Security Selection} \qquad \sum_s w_s^P \cdot \left(R_s^P - R_s^B\right) \tag{69–7}$$

Notice that while the contribution of each sector to asset allocation changes, the total asset allocation outperformance remains the same as long as $\sum_s w_s^P = \sum_s w_s^B$.

The constraint that the sum of the portfolio and the benchmark sector weights are equal to one necessitates the comparison of the benchmark sector returns with the overall benchmark return. If leveraging is allowed, such that there is no constraint on each sector's weight, then each overweighted sector with a positive return should indeed have a positive contribution to outperformance. In such a case, we do not need to compare the return of each sector to the return of the benchmark and Eqs. (69–4) and (69–5) apply. In practice, however, leverage constraints do exist (usually dictated by risk constraints), and neither the benchmark return nor zero is a generally appropriate choice for the hurdle rate for each sector. In the following discussion, we will use the term R^H generically for the hurdle rate. This formulation describes both above models while allowing for extra flexibility. A choice of $R^H = 0$ gives the original Brinson model in Eqs. (69–4) and (69–5), while a choice of $R^H = R^B$ gives the model in Eqs. (69–6) and (69–7).

Recursive Allocation

Most large portfolios have many management layers by which allocation decisions are made successively. For example, the global strategist can specify the allocation into global markets, the U.S. strategist can determine the allocation to major asset classes in the U.S. (equities, bonds, commodities, etc.), the fixed income strategist can determine the allocations into the various sectors, and so forth.

In such a case, what we called security selection above contains not only security selection, but also further asset allocation, as well as security selection for each subsector. In fact, each sector can be considered as a smaller portfolio for which the above performance breakdown equations can be applied recursively. For this reason we will use the term "Sector Management" instead of "Security Selection," and we will reserve the term "Security Selection" for the last layer of management when no further sector decomposition occurs.

For each sector, its contribution to the sector management from the level above, $w_s^P \cdot \left(R_s^P - R_s^B\right)$, is recursively split into the following components:

$$\text{Asset Allocation} \qquad w_s^P \sum_r \left(\frac{w_r^P}{w_s^P} - \frac{w_r^B}{w_s^B}\right) \cdot \left(R_r^B - R_s^H\right) \tag{69–8}$$

$$\text{Sector Management} \qquad \sum_r w_r^P \cdot \left(R_r^P - R_r^B\right) \tag{69–9}$$

Typically, the benchmark sector return R_s^B is used as the hurdle rate as for the calculation of asset allocation to subsectors. In this fashion, we can keep decomposing sector management outperformance until we reach the last layer of portfolio management. Since at each level the decomposition is complete, the total outperformance decomposition is also complete. This algorithm has two of the three required properties of performance attribution: additivity and completeness. As we will see in the following discussion, it also has sufficient flexibility to be applied under different management structures such that it is considered to be fair, thereby satisfying all three requirements of performance attribution.

The fundamental advantage of the sector-based attribution methodology is its flexibility. The ability to analyze portfolio allocations along an arbitrarily specified market partition makes it possible to customize the model to fit many different types of portfolios and management styles. The main disadvantage of this approach is that it analyzes yield-curve and spread returns within the same market partition using market value weights, something that does not correspond to standard fixed income portfolio management practice.

Factor-Based Attribution

The "sector-based" attribution is gradually losing ground to a "factor-based" decomposition of the investment universe, where the return of the security in the portfolio/benchmark is decomposed into the contributions of common risk factors plus a residual. The residual represents the return not captured by the risk factors. The coefficients of the factors, α_k, are called loadings or sensitivities of the portfolio to each factor, f_k. Typically, the decomposition is linear and is represented as:

$$R^P = \sum_k \alpha_k^P f_k^P + \varepsilon^P$$

Such risk factors for fixed income securities include interest rates, implied volatility, spreads, etc., and the loadings are the corresponding sensitivities to the exposure of each factor (option-adjusted duration, partial (key-rate) durations, Vega, spread duration, and related measures). Factor-based attribution essentially entails the decomposition of outperformance to the contribution of each risk factor.

$$R^P - R^B = \sum_k \left(\alpha_k^P - \alpha_k^B\right) \cdot f_k^P + (\varepsilon^P - \varepsilon^B) \tag{69–10}$$

Pure factor-based attribution systems attempt to use a set of factors that can explain all of the systematic return of a portfolio. In this case the excess return is idiosyncratic and therefore quite small for a well diversified portfolio. The disadvantages of this approach are that it does not attribute idiosyncratic returns of small portfolios to security selection decisions, and there is usually little flexibility in defining the risk factors. The latter shortcoming may be overcome with factor remapping,[5] which allows each portfolio manager to attain a personalized view of risk and return decomposition.

A Unified Framework for Performance Attribution

We will now combine the ideas we have developed in the preceding sections into a unified framework that blends the sector-based and the factor-based attribution. Models using this framework, such as the Barclays Capital Hybrid Performance Attribution model, are favored by portfolio managers since they can account for the complex management structures of large diversified portfolios. The framework offers enhanced flexibility in defining arbitrary hierarchical partitions along which sector allocation decisions are expressed. It allows the portfolio managers to achieve the best match to their investment decision-making process. It is a conceptually simple recursive algorithm that can be described in three steps: return splitting, factor return attribution, and recursive application. We explain these steps below.

Step 1: Return Splitting

The total return of the portfolio and the benchmark is split into the linear contributions of factors.[6]

$$R^P = \sum_k \alpha_k^P f_k^P \qquad R^B = \sum_k \alpha_k^B f_k^B$$

Note that residual is included here as one of the factors with a loading of one.

5. António Baldaque da Silva, "Risk Attribution with Custom-Defined Risk Factors," *Barclays Capital Publications*, August 2009.
6. Successive valuation used for the return splits is discussed in Chapter 70.

Step 2: Factor Return Attribution

The factors from step 1 are categorized as either common or allocated. We denote the set of common factors by C and the set of allocated factors by A and write the total outperformance as:

$$R^P - R^B = \left(\sum_{k\in C} \alpha_k^P f_k^P - \sum_{k\in C} \alpha_k^B f_k^B\right) + \left(\sum_{k\in A} \alpha_k^P f_k^P - \sum_{k\in A} \alpha_k^B f_k^B\right) \tag{69–11}$$

The outperformance from each factor is then handled separately. For each factor, we partition the investment universe into sectors[7] and decompose the outperformance from the factor.

$$\alpha_k^P f_k^P - \alpha_k^B f_k^B = \sum_s \alpha_{k,s}^P f_{k,s}^P - \sum_s \alpha_{k,s}^B f_{k,s}^B \tag{69–12}$$

Outperformance from common factors is explained using bottom-up aggregation, namely via net exposures to a factor at each level of the aggregation. Furthermore, if a factor is truly common, where the factor return in the portfolio is identical to the factor return in the benchmark, then the contribution of the factor to portfolio outperformance can be written as:

$$\alpha_k^P f_k^P - \alpha_k^B f_k^B = \sum_s \left(\alpha_{k,s}^P - \alpha_{k,s}^B\right) \cdot f_{k,s} \tag{69–13}$$

This breakdown allows the performance of the portfolio due to the common factors to be categorized and aggregated to the portfolio level. In this way, a more detailed explanation of the factor and its impact to the total portfolio is possible than if the return were split between sectors. For example, exposure to the yield-curve is typically managed at the portfolio level by determining first the overall duration over/underweight vs. the benchmark and then determining where on the yield-curve to take the extra exposure. The strategy may be designed to take advantage of flattening or steepening in the yield-curve, and only measurement of these effects at the portfolio or sub-portfolio level is meaningful.

Outperformance from allocated factors is explained using the following allocation methods: absolute allocation and relative allocation. We discuss each below.

Unlike common factors, allocated factors may have different realizations for different securities or sectors even if they broadly capture the same type of risk exposure. For example, credit-spread, whose level depends on the particular securities within a sector, is a factor of this type. In the absolute allocation framework, the total portfolio exposure to each factor is determined by all sector managers. Each sector manager may take a different view as to the expected direction of each factor. In this case, asset allocation is solely determined by the net sector exposure to a particular factor:

$$\text{Asset Allocation} \qquad \sum_s \left(\alpha_{k,s}^P - \alpha_{k,s}^B\right) \cdot f_{k,s}^B \tag{69–14}$$

$$\text{Sector Management} \qquad \sum_s \alpha_{k,s}^P \cdot \left(f_{k,s}^P - f_{k,s}^B\right) \tag{69–15}$$

7. A different partition may be used for each factor.

In the relative allocation framework, the total exposure to each factor is determined at the portfolio level (or the higher hierarchical level). The asset allocator subsequently determines the sector exposures to the factor subject to the constraint imposed by the portfolio exposure. Each sector may take a different view as to the relative movement of each factor against the overall benchmark factor return.

Asset Allocation
$$\alpha_k^P \cdot \sum_s \left(\frac{\alpha_{k,s}^P}{\alpha_k^P} - \frac{\alpha_{k,s}^B}{\alpha_k^B} \right) \cdot \left(f_{k,s}^B - f_k^H \right) \tag{69–16}$$

Sector Management
$$\sum_s \alpha_{k,s}^P \cdot \left(f_{k,s}^P - f_{k,s}^B \right) \tag{69–17}$$

Top-level Exposure
$$\left(\alpha_k^P - \alpha_k^B \right) \cdot f_k^H \tag{69–18}$$

Notice that in the relative allocation framework, the factor hurdle rate f_k^H essentially becomes a common factor.

Step 3: Recursive Application

The sector management terms from top-down allocations, $f_{k,s}^P - f_{k,s}^B$, can be now decomposed separately using the above algorithm recursively.

At the last stage of the decomposition, in which a sector is not decomposed further into subsectors, the sector management term becomes security selection. The top-down decomposition can be applied one last time to break down the security selection outperformance of a sector into the contributions of individual securities. In this case the management term is typically zero, since the factor driving the return of the same security in the portfolio and the benchmark is the same.

An Example of Hybrid Performance Attribution

To illustrate how this algorithm can be applied in practice, consider a very simple model in which the return of a security is split into two components: the time return that is measured by the yield of the security and a market return that is measured as the duration of the security times the negative of its yield change. This decomposition may not be complete, so it is reasonable to assume the presence of a residual.

$$R_i = Y_i \, \Delta t - D_i \, \Delta Y_i + \varepsilon_i \tag{69–19}$$

The portfolio (or benchmark) return is the weighted average return of the securities in the portfolio (or benchmark). The summation extends over a universe defined by the union of securities in the portfolio and benchmark. Securities not present in either get correspondingly zero weight.

$$\begin{aligned} R^P &= \sum_i w_i^P R_i = \sum_i w_i^P Y_i \, \Delta t - w_i^P D_i \, \Delta Y_i + w_i^P \varepsilon_i \\ R^B &= \sum_i w_i^B R_i = \sum_i w_i^B Y_i \, \Delta t - w_i^B D_i \, \Delta Y_i + w_i^B \varepsilon_i \end{aligned} \tag{69–20}$$

Aggregation of yield and duration is the usual weighted average; however, yield changes must be aggregated using duration contribution weights to retain their natural interpretation.

$$Y^P = \sum_i w_i^P Y_i \qquad Y^B = \sum_i w_i^B Y_i$$
$$D^P = \sum_i w_i^P D_i \qquad D^B = \sum_i w_i^B D_i \tag{69–21}$$

$$\Delta Y^P = \sum_i \frac{w_i^P D_i}{D^P} \Delta Y_i \qquad \Delta Y^B = \sum_i \frac{w_i^B D_i}{D^B} \Delta Y_i \tag{69–22}$$

We can now rewrite the portfolio and benchmark returns using top-level analytics:

$$R^P = Y^P \Delta t - D^P \Delta Y^P + \sum_i w_i^P \varepsilon_i$$
$$R^B = Y^B \Delta t - D^B \Delta Y^B + \sum_i w_i^B \varepsilon_i \tag{69–23}$$

Let us assume that time return (carry) and residual are allocated as common factors.

$$\text{Carry} \qquad (Y^P - Y^B) \cdot \Delta t \tag{69–24}$$

$$\text{Residual} \qquad \sum_i \left(w_i^P - w_i^B\right) \cdot \varepsilon_i \tag{69–25}$$

Market return is managed by allocating duration exposure $w_s^P D_s^P$ to a set of sectors and allowing managers to pick securities within each sector.

If the top-level portfolio duration is not constrained and is completely determined by the choices of the sectors' net duration exposures, we should use the absolute allocation algorithm by setting $\alpha_k \leftarrow D$, $\alpha_{k,s} \leftarrow w_s D_s$, $f_{k,s} \leftarrow -\Delta Y_s$. The duration and yield change of each sector in the portfolio and the benchmark are calculated in the same weighted average fashion we discussed above. Since the asset allocation agent is free to determine the duration exposure of each sector, there is no hurdle rate and the total outperformance is solely distributed between asset allocation and security selection.

$$\text{Asset Allocation} \qquad -\sum_s \left(w_s^P D_s^P - w_s^B D_s^B\right) \cdot \Delta Y_s^B \tag{69–26}$$

$$\text{Security Selection} \qquad -\sum_s w_s^P D_s^P \cdot \left(\Delta Y_s^P - \Delta Y_s^B\right) \tag{69–27}$$

On the other hand, if the net duration of the portfolio is actively managed, we need to use the relative allocation method. In this case, we set the hurdle rate equal to the benchmark yield change.

$$\text{Asset Allocation} \qquad -D^P \cdot \sum_s \left(\frac{w_s^P D_s^P}{D^P} - \frac{w_s^B D_s^B}{D^B}\right) \cdot \left(\Delta Y_s^B - \Delta Y^B\right) \tag{69–28}$$

Security Selection $$-\sum_s w_s^P D_s^P \cdot \left(\Delta Y_s^P - \Delta Y_s^B\right) \tag{69–29}$$

Top-level Exposure $$-(D^P - D^B) \cdot \Delta Y^B \tag{69–30}$$

APPLICATIONS OF PERFORMANCE ATTRIBUTION

Beyond its stated goal of attributing portfolio outperformance to the actions of agents, detailed and flexible performance attribution can bring clarity to the process of portfolio management by systematically exposing sources of risk and performance. By linking ex-post outperformance contributions to ex-ante views and management decisions, a manager can identify unanticipated sources of risk and return and adjust the management process accordingly. In addition, by providing the recursive decomposition of outperformance into the various contributing factors, it facilitates the discovery and correction of data errors that are not uncommon in large financial accounting systems. In the rest of this chapter we will illustrate such applications of performance attribution in the context of a particular portfolio.

Performance Attribution as a Portfolio Management Tool

Consider the following example. A portfolio manager has the mandate to track the Barclays Capital Global Aggregate G4 Index and has the latitude to implement certain market views in order to enhance the portfolio returns, as long as the standard deviation of portfolio minus benchmark returns (Tracking Error Volatility or TEV) stays below 40 bp per month. At a specific point in time, the manager is bullish on the Japanese yen, negative on the euro and neutral on the U.S. dollar and the British pound. She believes that global rates are falling. She has no sector views except in the U.S. markets, where she likes corporates but dislikes the securitized sector. According to her mandate and her views, she constructs a portfolio with the following characteristics:

- The portfolio has a 5% overweight (vs. the benchmark) in the yen, a 5% underweight in the euro and is flat in U.S. dollars and British pounds.
- The portfolio interest-rate option-adjusted duration (OAD) is about one year longer than that of the benchmark.
- Within the U.S. market, the portfolio has a 5% overweight in corporates, a 5% underweight in securitized, and is flat in the U.S. Treasury and government-related sectors.

We created this portfolio in the Barclays Capital POINT system and used the Global Risk Model in POINT to estimate the portfolio tracking error volatility relative to its benchmark as 32 bp per month. Since this is below the 40 bp per month risk budget the portfolio is acceptable.

EXHIBIT 69–1

Total Portfolio Outperformance

Global Outperformance (bp)	
Portfolio Return	188.7
Benchmark Return	150.0
Total Outperformance	**38.7**

Source: Barclays Capital POINT

We subsequently ran the POINT hybrid performance attribution model over one month and produced a detailed performance attribution report. This report begins by reporting the total portfolio and benchmark returns over the month (+188.7 bp and +150.0 bp respectively) as well as their difference, +38.7 bp, the total portfolio outperformance (Exhibit 69–1). The report then proceeds to decompose the total outperformance into the contributions of the various portfolio exposures and market performance. The decomposition is hierarchical to allow the portfolio manager to first get a broad understanding of the sources of outperformance and then dive into the specific details. In Exhibit 69–2, we see a first decomposition of the portfolio total outperformance on a global level into three components: FX Allocation and Hedging (+28.3 bp), Local Market Allocation (–8.7 bp), and Local Market Management (+19.1 bp). In Exhibit 69–3, the Local Market Management component is further decomposed into contributions from Yield-Curve exposures (+20.6 bp), Asset Allocation (+0.2 bp) and Security Selection (–1.7 bp).

Outperformance from Currency Exposures

The +28.3 bp outperformance from FX allocation and hedges indicates that the manager's FX views were broadly correct. In Exhibit 69–4 we can see that,

consistent to the manager's predictions, the yen rallied and the euro fell versus the U.S. dollar. The analysis also shows that the portfolio maintained a net exposure of +5% in the yen and –5% in the euro with little drift. In particular, the yen outperformed the U.S. dollar by 319.4 bp in the period, a figure that includes the change in the FX spot rate and the short-term interest rate differentials between the two currencies.[8] Since the yen is overweighted by 5% on average, a quick calculation estimates the outperformance contribution as 5% × 319.4 = +16.0 bp. This calculation is not exact, since the attribution model used in this example employs daily frequency and compounding as we have discussed previously. Such simple calculations are acceptable when the net exposure does not fluctuate significantly over the attribution period and will be used throughout this example. In this case the reported yen contribution of +16.1 bp in Exhibit 69–4 is within 1 bp of the result of simple calculation.

Similar analysis can be carried out for the underweight to weakening euro which contributes outperformance of +12.0 bp. The fact that the British pound also weakened generates no outperformance because the portfolio net exposure to the British pound was designed to be zero. Finally, the completeness of FX outperformance decomposition is ensured by accounting for the interaction effect between FX and local returns. The cross-term is normally small. In this case, it is only +0.2 bp.

Outperformance from Allocation to Local Markets

Allocation to local markets evaluates a portfolio manager's decision to under-/overweight a local bond market. In this example its contribution is –8.7 bp. Exhibit 69–5 shows the major contributors to be the yen and euro markets. By attempting to overweight the yen and underweight the euro using cash instruments (i.e., without using FX forwards), the portfolio also took on an overweight in the yen local market and an underweight in the local euro-zone market. The yen market overweight is not a good decision since its local return over the deposit rate is

8. See Chapter 71 for a detailed discussion

only +64.2 bp, much lower than the benchmark local return over deposit of +164.1 bp. Therefore, it generates an underperformance that can be approximately calculated as (64.2 – 164.1) × 5% = –5.0 bp, as reported in the second to last column. The euro market underweight is not good either, since the local market had a return of +239.2 bp, significantly higher than the benchmark return of +164.1 bp. It results in an underperformance estimated as (239.2 – 164.1) × –5% = –3.8 bp. The actual contribution is –3.7 bp, as reported in the second to last column and together with the –5.0 bp of the yen market contribution fully explain the Local Markets Allocation outperformance component.

Separation of the FX and Local components of global markets allows the measurement of outperformance under several styles of management. In some portfolio management structures, the FX exposure of the portfolio is managed separately from the local market exposure of the portfolio using derivative instruments such as FX forwards. However, in our example, the exposures to the local markets might be thought as incidental to the manager's FX views and a result of not properly differentiating the views on FX versus the views on the local market performance. In this case, it might make sense to combine the two contributions and allocate 28.3 – 8.7 = +19.6 bp of outperformance to the views on the currency markets.

Outperformance from Management of Local Markets

Once the allocation into each local market is determined, local market management measures how well the portfolio performed versus its benchmark within the same local market. From Exhibit 69–3, we already know that the dominant contributor is yield-curve exposures with +20.6 bp. Exhibit 69–6 offers more details by each local market.

We can see that positive yield-curve outperformance came primarily from the U.S. dollar and the euro markets, whereas the British pound curve exposure

resulted in a loss of –11.5 bp. We also see that asset allocation was not a significant driver of performance. Security selection decisions within each local market were significant, although the net result across all currencies was small at –1.7 bp. In particular, the selections within the U.S. dollar and British pound portion of the portfolio contributed positively, +5.9 bp and +6.2 bp respectively, but the selections within the euro portion of the portfolio negated these gains by contributing –13.3 bp.

Outperformance Due to Yield-Curve Exposure

Focusing on the large yield-curve outperformance contribution, the manager wants to understand how her directive to go long duration by one year globally was implemented, and analyze the impact on each individual market. Exhibit 69–7 shows the yield-curve outperformance breakdown for the U.S. dollar portion of the portfolio.

Individual market reports are unscaled by the value of the holdings in each market in order to evaluate single-market managers on an equal basis. Looking at each market in absolute terms allows us to reveal useful information about the management within each market, even for markets that constitute a small portion of the overall portfolio and their contributions to total portfolio outperformance are not significant. To translate the absolute unscaled numbers contained in the local reports into their contributions to total portfolio outperformance, one has to multiply such numbers by the corresponding market weight in the portfolio. In this example, the currency weights can be found in the Global Outperformance by Currency report in Exhibit 69–6; they are 45.5% for the U.S. dollar, 23.2% for the euro, 25.6% for the yen, and 5.8% for the British pound market.

The yield-curve report in Exhibit 69–7 contains a lot of information, but the manager can quickly see that the U.S. Treasury curve experienced bull-flattening with long rates falling in excess of 40 bp (third column from the left). She can also see that the portfolio is generally long duration by about 0.5 years (4.66 vs. 4.18). This is consistent with the general desire to be long duration, and with rates generally falling, it creates outperformance. More precisely, the yield change at the average maturity point of the benchmark is –31.6 bp. Multiplied by the (negative of) the average duration overweight of 0.48 years results in approximately +15.2 bp of outperformance contribution. The daily algorithm calculates that this number is actually +14.6 bp (top of the second to last column) by taking into account that duration exposure fluctuated during the period. The total U.S. dollar curve outperformance, accounting for the re-shaping of the yield-curve and the contributions from carry, is calculated to be +24.6 bp. Most of the additional outperformance comes from a butterfly position on the curve, where an overweight of the 20 year point of about 1.36 years is partially offset with underweighting the 5, 10, and 30 year points. Since the 20 year point is the one with the largest yield drop (–48.7 bp), this butterfly position results in additional outperformance. The algorithm calculates and reports the excess contribution of each curve point separately.

Source: Barclays Capital POINT

The manager should be concerned that such a large component of total outperformance comes from an inadvertent position in the re-shaping of the U.S. curve (about +4.7 bp, estimated as the non-parallel U.S. curve outperformance 24.6 – 14.3 = +10.3 bp, times the U.S. dollar market weight of 45.5%) and should seek to control exposure to the various parts of yield curves more carefully.

Exhibit 69–8 displays the yield-curve reports for the other three currencies. The euro curve outperformance analysis is very similar to the U.S. dollar one. There is duration overweight of about 1 year, as well as a butterfly position. Like the U.S. dollar curve, the euro curve also bull-flattens, resulting in (unscaled) outperformance of +77.4 bp and a contribution to total outperformance of +17.9 bp (remember that the average portfolio weight of the euro market is 23.2%). The yen has an even bigger duration overweight, about 2.7 years, but the curve movement is not as dramatic, with average yields falling about 7 bp. The portfolio contains significant curve reshaping positions as well, with the 20 year point being overweighted by more than 3 years, while the 20 year point is underweighted by about 1.7 years. Nevertheless, the yen curve change is not sufficiently pronounced and generates only +11.8 bp of (unscaled) outperformance, contributing +3.0 bp to the total outperformance (the average portfolio weight of the yen market is 25.6%). The picture is completely different for the British pound. Here, the portfolio has a significant duration underweight of about 3.8 years, combined with a strong bull-flattening move of the British pound yield-curve (a yield change of –44.9 bp at the long end). This underweight results in a dramatic (unscaled) underperformance of –199.2 bp. The small average portfolio weight of the British pound market (5.8%) prevents this from being a major drag in the portfolio performance but even so its contribution to total outperformance is a significant –11.5 bp.

At this point, it should be clear to the portfolio manager that understanding and managing the detailed exposure to the yield-curve of each currency is of paramount importance for proper control of the portfolio performance. She may also decide that global curve management is so important that it has to be managed before any local allocation and management decisions are made. In this case, a different attribution algorithm must be used, one that excludes yield-curve outperformance from the Local Market Allocation and Local Management Components. A detailed discussion on this type of analysis can be found in Chapter 71.

Asset Allocation and Security Selection

The manager now shifts her attention to the remaining sources of outperformance. First, she wants to understand how her views on the performance of U.S. assets panned out. From the "Global Outperformance by Currency" report of Exhibit 69–6, she already knows that U.S. dollar asset allocation contributed –2.5 bp to total outperformance. Exhibit 69–9 displays the U.S. Dollar Asset Allocation report, where we can see that most of the underperformance is caused by the overweight to corporate bonds. Remember that all numbers in this page are un-weighted; that is, they have to be scaled by the 45.5% portfolio weight of the

U.S. market allocation in order to convert them into contributions to total portfolio outperformance. In particular, the 5% overweight sought to U.S. corporate bonds during the portfolio construction is represented here as an overweight of 10.9% (30.9% – 19.8% = 11.1%, approximately equal to 5%/45.5%), and the –2.5 bp of underperformance is reported as –5.5 bp (approximately equal to –2.5 bp/45.5%). The corporate sector contributes –5.2 bp, something that can be explained by the significant underperformance of the corporate sector in the benchmark (–70.2 bp) relative to the benchmark itself (–22.0 bp). The approximate calculation results in 11.1% × (–70.2 + 22.0) = –5.35 bp, close to the –5.2 bp reported. The Treasury and government-related sectors have no contribution to asset allocation, as their weights are matched exactly between the portfolio and the benchmark, as designed. Finally, the securitized sector has minimal contribution to asset allocation, despite the significant underweight, because its performance (–19.0 bp) is close to that of the benchmark (–22.0 bp).

The same report also lists the contribution of each sector to security selection. We see that once again, the corporate sector is the dominant contributor with +11.1 bp out of the total +13.0 bp of security selection in the U.S. dollar market. To further understand the sources of security selection outperformance, the manager studies the detailed U.S. Dollar Security Selection report displayed in Exhibit 69–10. This report lists the chosen securities in each sector and their excess-of-curve return. We can see that the manager responsible for security picks in the U.S. corporate sector has indeed picked mostly securities whose excess returns beat the benchmark. One notable exception is the 6.45% 2037 Comcast bond, which represents 10.1% of the portfolio holdings in this sector (an overweight of 10% versus the benchmark) and which experienced –280.0 bp of excess return (much worse than the benchmark, which lost only 70.2 bp).

To estimate the contribution of the bond to the security selection outperformance coming from U.S. corporate bonds, one must take into account the weight of the corporate sector in the U.S. portfolio, which is 30.7%, to get 30.7% × 10% × (–280.0 + 70.2) = –6.4 bp. After scaling by the 45.5% weight of the U.S. portfolio, we calculate the contribution of the particular Comcast bond to global outperformance as 45.5% × –6.4 bp = –2.9 bp. This is quite significant and highlights the importance of name selection in a portfolio with a relatively small number of positions.

The manager also takes a look at the details of security selection in the euro market, which, as reported in Exhibit 69–6, reduces the total outperformance by a significant 13.3 bp. The report in Exhibit 69–11 lists the security selection outperformance as –57.4 bp (which scaled by the market weight of the euro market of 23.2% is equal to –13.3 bp) and identifies Italian government bonds as the main culprits. The fact that, absent any specific direction otherwise, the euro government sector was constructed by mostly Italian government bonds, leading to significant underperformance because of sovereign credit deterioration in Italy, indicates that the manager should attempt to take control of country exposure within the euro sector.

Source: Barclays Capital POINT

By now, the manager has a good understanding of most major contributors to the outperformance of the portfolio and has also reached some useful conclusions regarding the management of a small global portfolio.

- Yield-curve exposure is the dominant risk factor and must be managed explicitly in each currency.
- It is not sufficient to manage yield-curve exposure using just the duration. Exposure to curve re-shaping must also be controlled carefully.
- It may make sense to manage yield-curve exposure globally and not allow it to be determined by local allocation and management decisions.
- Name risk is very significant in a small portfolio; exposure to corporate issuers must be scrutinized and questionable names should be excluded.
- Country risk in certain areas such as the euro-zone must be managed separately.

Further insight can be gained by using a mode of performance attribution in which returns and outperformance are fully decomposed using all available analytics from pricing models. In this model, any part of outperformance that cannot be explained by analytics is reported as residual. This Fully Analytical model will be explained in detail in Chapter 70. Using this model, we get the local management details shown in Exhibit 69–12.

Comparing it with the report of Exhibit 69–3 we see that Local Market Management Details panel has changed. While the yield-curve contribution remains at +20.6 bp, asset allocation is now –0.9 bp instead of +0.2 bp, and security selection is now –2.2 bp instead of –1.7 bp. New terms have appeared, in particular Implied Volatility with +0.9 bp contribution, Mortgage with –3.7 bp

contribution, and Residual with a prominent +4.4 bp. The Fully Analytical model also offers more clarity into sources of outperformance beyond the yield-curve, allowing users to understand the sources of the various types of outperformance; it will be discussed in detail in Chapter 70. In this example we will review only the Euro Security Selection report shown in Exhibit 69–13. We can see that not only is the portfolio concentrated on Italian government bonds, but that it also contains bonds of very long maturity, further overweighting the entire European government sector in terms of spread duration exposure. This may lead the manager to draw yet another conclusion: The spread duration exposure of sectors with credit risk must be carefully controlled.

Performance Attribution as a Data Quality Tool

A comprehensive and detailed performance attribution system serves as a magnifying lens for data quality problems and allows users to pinpoint and correct such issues quickly.

The report of Exhibit 69–13 shows that one particular Italian government bond (Issue IT0004513641) is almost single-handedly responsible for the entire reported residual. Indeed, it contributes +17.4 bp of residual to the euro portfolio, which, when scaled by the euro portfolio market weight of 23.2%, results in +4.0 bp of portfolio-level residual (out of the total of +4.4 bp reported in Exhibit 69–12). A diligent manager will promptly investigate such residuals. They may mean one of the following four things:

- Incorrect total returns. This can be caused by missing or incorrect prices, transaction errors, incorrect corporate actions, etc.
- Missing or inaccurate analytics produced in the security valuation process
- Attribution model deficiencies wherein certain contributing factors are not captured by the factor return decomposition
- Issues with the attribution algorithm or its implementation

All four are extremely important for the portfolio manager to know. Over time, model deficiencies will presumably be corrected, leaving data quality problems in the form of bad returns or bad analytics to be the primary cause of attribution residuals.

In the case of this portfolio, a quick investigation reveals that the offending bond had a coupon payment of 2.50% that has been recorded twice. The price of the bond on the coupon payment date was approximately 110; therefore, one would expect a residual of +227.3 bp at the bond level. Indeed, after taking into account the net weight of the bond, the residual contribution of the bond to the euro portfolio is $44.0\% \times (18.3\% - 0.5\%) \times 227.3 = +17.8$ bp, very close to the +17.4 bp of reported residual. Re-running the report after correcting the double entry produces a mostly identical report (Exhibit 69–14) to the one before (Exhibit 69–12), except that the return of the portfolio is lower by the correction

amount (+4.2 bp), the outperformance is +34.5 bp instead of +38.7 bp, and the residual term has been reduced correspondingly from +4.4 bp to +0.2 bp.

Data problems have the potential to affect the quality of outperformance measurement of a portfolio significantly, as well as its breakdown to the various sources. Proper use of an analytics-based attribution platform can help identify and correct potential issues promptly.

KEY POINTS

- Performance measurement and attribution is an important function of the investment process. It helps bring clarity to the sources of portfolio risk and performance and identify the contributions of individual decision-makers.
- A successful performance attribution algorithm should satisfy three important requirements: additivity, completeness, and fairness.
- A good attribution system should have a calculation and compounding frequency that corresponds to the dynamics of modern portfolio management. This normally means daily frequency for an actively managed fixed income portfolio.
- A good attribution system should have the flexibility to accommodate the wide range of portfolio management styles. The best attribution is an analysis that best matches the portfolio management decision making process.
- Performance attribution algorithms typically follow either a sector-based allocation or a factor-based allocation, but neither is sufficient to cope with the complexity of modern portfolio management.
- Algorithms that combine the sector-based and the factor-based attribution have the flexibility to adapt to the particular management structure of most fixed income and equity portfolios.

CHAPTER
SEVENTY

PERFORMANCE ATTRIBUTION FOR PORTFOLIOS OF FIXED INCOME SECURITIES

In contrast to the simple and opaque nature of equities, fixed income securities can be thought of as structured investments which promise to pay a stream of cash flows. The magnitude of cash flows can be fixed, or may depend on observable variables (e.g., realized inflation, principal prepayments of mortgage loans, or the price of the security itself for securities with call/put features). This quasi-formulaic nature of fixed income securities allows their present value to be expressed as a (generally stochastic) function of economic variables—most prominently interest rates and credit spreads—which can be calibrated to observed market prices of reference securities to generate a "pricing model." In other words, a pricing model is a function that expresses the present value of a

The authors would like to thank Lev Dynkin for introducing us to the concept of performance attribution, Jay Hyman for many insightful ideas over the years and Attakrtit Asvanunt who was instrumental in the development of many concepts in this chapter.

fixed income security (or derivative contract) as a function of economic variables. This function can be also used to estimate the sensitivities of the present value to changes in the underlying variables. Such sensitivities, generically called *analytics* and known as *greeks* in the options world or *duration/convexity* in the bond world, can and are being used as loadings to the pricing factors driving returns during performance decomposition and attribution of fixed income portfolios.

In this chapter we discuss in detail how the performance of a portfolio of fixed income securities relative to a benchmark can be analyzed using the hybrid performance attribution algorithm described in the Chapter 69. The hybrid methodology that combines factor-based attribution with the traditional Brinson method is particularly appropriate for fixed income securities whose return usually includes a significant component driven by a common factor, interest rates. In this chapter, we will focus on attribution over a single period only. As discussed in Chapter 69, a single period is one business day for the majority of fixed income systems. Methods for compounding single period attribution results over longer periods of time will be discussed in detail in Chapter 71.

We begin the discussion by using a generic pricing model in order to split the return of a fixed income security into the contributions of the various factors driving the security return. We discuss in detail the treatment of the most important factors such as interest rates, implied volatility and credit spreads. Two important asset classes with special characteristics, mortgage-backed securities and inflation-linked bonds, are discussed separately. We then show how the flexible hybrid attribution framework can be applied in several ways to accommodate various types of fixed income portfolios and styles of portfolio management.

In this chapter we restrict the analysis to single-currency portfolios. The complications arising from investing in multiple currencies will be discussed in the Chapter 71. All performance attribution reports have been generated using the Barclays Capital Hybrid Performance Attribution (HPA) model[1] as implemented in POINT, the Barclays Capital portfolio analytics and modeling platform.[2]

RETURN SPLITTING

Securities with deterministic cash flows are priced by discounting the cash flows off a reference yield-curve. When future cash flows are not known but can be reasonably predicted by modeling them as functions of economic variables (most commonly interest rates) and security characteristics, more complex statistical diffusion models are used. Such models produce a set of projected interest rate paths that are consistent with the current yield-curve and the market implied

1. For details of the model, see Anthony Lazanas, Chris Sturhahn, and Pamela Zhong, *The Barclays Capital Hybrid Performance Attribution (HPA) Model* (Barclays Capital Publications, October 2010).
2. Both Hybrid Performance Attribution and POINT are registered trademarks of Barclays Capital.

volatility of liquid interest-rate options. Projected cash flows on each path are discounted at the corresponding discount factors, and the present value of the security is calculated as the average present value across all interest-rate paths. In this case, the present value of a security is a function of interest rates, their implied volatility and possibly other variables in the model.

A pricing model produces the "model value" of a security. In the case of securities such as derivatives that are traded over-the-counter, the model value is usually used to mark-to-market positions in the security. When a security is publicly traded, its market price generally does not agree with the model price. To make them equal, model parameters are calibrated to match the market price. For example, in the case of bonds, this usually entails additional discounting of cash flows at a flat rate across all maturities. In the majority of models, in which cash flows are discounted at a risk-free reference yield-curve (the government or swap yield-curve in a particular currency), this additional discounting rate is the well-known option-adjusted spread (OAS), which captures the extra discounting required to account for credit, liquidity and other types of risks. Analytics produced by such a model are therefore known as option-adjusted analytics.

Generically, a pricing model can be expressed with the following formula:

$$MarketValue = f\,(Time,\ YC,\ Vol,\ Other,\ OAS)$$

Here, *YC* stands for yield-curve, *Vol* for implied volatility, and *Other* for any other market factors or parameters that the pricing model is using.

For a single-currency portfolio, the analysis begins with splitting the return of each portfolio position into the contributions of various factors. Most pricing systems provide the first-order sensitivity of the market value of a position to the underlying risk factors. Sometimes second-order sensitivities to particular factors (such as interest-rate convexity) are also reported. Using these sensitivities, the return of a particular position is approximated as a linear combination of the contributions of each pricing factor, for example:

$$R \approx \frac{\partial f}{\partial Time}\Delta Time + \frac{\partial f}{\partial YC}\Delta YC + \frac{1}{2}\frac{\partial^2 f}{\partial YC^2}\Delta YC^2 + \frac{\partial f}{\partial Vol}\Delta Vol + \frac{\partial f}{\partial OAS}\Delta OAS$$

Although some pricing systems do provide additional sensitivities (e.g., spread convexity, or sensitivities to some of the "other" pricing factors such as prepayment speed for mortgage securities) most of the times the difference between the actual return of a position (as reported in the accounting system of the portfolio) and the above approximation is non-negligible. Such difference, usually referred to as *Residual*, is attributable to sensitivities to unaccounted model inputs and parameters, higher-order terms, cross-terms between factors, and very often in practice, data and calculation errors. Analyzing the residual and understanding whether it is legitimate or a result of data or calculation error is an important function of a performance attribution system. To help achieve that, sophisticated performance attribution systems use an alternative scenario-based

decomposition of returns, which by design is complete, i.e., has no residual. The return splitting exercise in such systems has two stages:

Stage I: Scenario-based return decomposition into broad categories

Stage II: Analytics-based return decomposition into fine categories

In Stage I, the scenario decomposition of one-period return[3] begins with the market value of the position at the beginning of the period and then moves one parameter at a time to the end-of-period value until all of the parameters have changed and the end-of-period market value is obtained. At each step, the market value of the security is obtained by fully recalculating its market value by changing one input parameter at a time. This stage divides the return into broad categories, as described in Exhibit 70–1.

Of course, this is not the only possible decomposition. Coarser or finer decompositions are also possible, but this particular one is a good compromise between computational complexity and informational content for most fixed income portfolios. In Stage II, the sensitivities of the security to various pricing model inputs (analytics) are used to decompose the return further. The combination of the two decompositions allows the residual to be split among the major return constituents providing more insight about its potential sources.

EXHIBIT 70–1

Typical Scenario-Based Return Decomposition

Surprise Return	The difference of actual cash flows and notional changes from model predictions
Time Return	The effect of elapsing time
Yield-Curve Change Return	The effect of changes in the yield-curve
Implied Volatility Change Return	The effect of changes in the implied volatility surface
Other Market Return	The effect of changes in any other market parameters
Spread Change Return	The effect of changes in the option-adjusted spread

3. As discussed in Chapter 69, attribution over longer periods of time requires compounding attribution results over smaller periods. The length of a single period should be consistent with the management style of the portfolio. Actively managed portfolios should use a short period, typically one day. Buy and hold portfolios should use longer periods such as one month or even one year. The algorithm we describe here can be applied for arbitrary period lengths. Nevertheless, bear in mind that using pricing analytics to manage exposure typically indicates an active management style which more often than not requires daily portfolio actions and therefore daily compounding of attribution results.

We will now discuss in more detail the various return constituents in the typical decomposition of Exhibit 70–1.

Surprise Return

Surprise return is relevant to securities whose cash flows and amount outstanding are not deterministic. For example, for mortgage-backed securities, it is prepayments that generate the random behavior of cash flows and amount outstanding; for inflation-linked securities, it is the dependence of cash flows on the reference inflation index. Security valuation models make assumptions about inputs to pricing models and use such projections to value securities until realized values are known. The return explained by running scenarios or using model analytics is the return that would be realized if the uncertain parameters were consistent with the model predictions. If the realized values of the parameters are different from the projected ones, the difference between the actual return and the return explained by the model is captured as surprise return.

Mortgage Prepayments Surprise Return

As an example, consider a mortgage-backed security that is trading at a price of 105 and zero accrued. The prepayment model projects a 2.4% prepayment over the next month (25% CPR), thus predicting a return due to prepayments of –11.4 bp.[4] If the actual prepayment is lower, say 1.3% (15% CPR) resulting in a prepayment return of –6.2 bp, the difference of +5.2 bp will be registered as prepayment surprise return. The model-expected –11.4 bp of prepayment return will be part of the time return component.

Inflation Surprise Return

As another example, consider an inflation-linked security that is trading at a price consistent with projected inflation for next month of 3.0%. If the actual inflation announcement is 3.5% it will give +4.2 bp[5] of inflation surprise return to account for the larger inflation accretion accumulated over the month relative to the projected inflation rate. This return is separate from any return resulting from presumably increased future inflation expectations caused by the higher-versus-expectations announcement. Such return is captured separately as inflation spread change as will be described below.

Time Return

Time return is the deterministic component of the return, i.e., the return predicted by the pricing model if market parameters remain unchanged.[6] For most fixed income securities, time return can be decomposed into yield-curve carry, spread carry and volatility decay. Inflation-linked securities also have inflation accretion

4. –11.4 bp = (par-105) * 2.4% / 105.
5. The exact calculation is (3.5%/12 – 3.0%/12) / (1 + 3%/12) = 4.16 bp
6. We discuss the definition of "unchanged" for the yield-curve later in this chapter.

and inflation spread carry. These time return components can be measured using analytics, as we will describe in detail in following sections.

Yield-Curve Change Return

Changes of interest rates affect securities returns primarily through the change of discount factors. In addition, some securities have cash flows that are modeled as functions of interest rates (mortgage-backed, floating-rate securities). The component of return that is due to the fluctuation of the yield-curve is captured by the yield-curve change return component. The exposure of the security value to the yield-curve is captured by its sensitivity to parallel shifts of the yield-curve, the option-adjusted duration (OAD), movements of a specified set of points (key-rate points) representing the yield-curve, the key-rate durations (KRDs), and its second-order sensitivity, option-adjusted convexity (OAC). In daily frequency attribution models the potential daily change of yields is limited (moves above 15 bp are very uncommon); therefore, the convexity contribution is typically much smaller than the duration contribution. For this reason, the effect of yield-curve convexity does not need to be explicitly measured.[7]

Yield-Curve Change Return Decomposition

How total yield-curve change return is broken down between duration and convexity depends to a large extent on the frequency at which the duration exposure of a portfolio is managed. In this example a daily frequency is assumed, consistent with the practice of the majority of portfolio managers. To understand the frequency implications, consider a portfolio with interest-rate duration of 5 and an interest-rate convexity of –2. Assume that over the two weeks, interest rates keep falling at 10 bp per business day for a total of 100 bp. The duration-convexity formula explains portfolio returns caused by changes in interest rates:

$$R^{\Delta YC} = -OAD \cdot \Delta r + \frac{1}{2} \cdot (OAC/100) \cdot \Delta r^2$$

where both the returns and the rates change are expressed in basis points.

Applying this formula for the entire two weeks results in the following:

Duration Return:	$-5 \times (-100) =$	+500 bp
Convexity Return:	$0.5 \times (-2/100) \times (-100)^2 =$	–100 bp
Total Return:		+400 bp

On the other hand, applying the formula daily generates quite a different breakdown. The daily algorithm must take into account additional complexities such as the duration drift of the portfolio, as well as compounding. It is not sufficient

7. For currencies with high volatility of yields, convexity can become a significant determinant even for daily returns. In such a case, it is straightforward to include convexity as an explanatory variable to the algorithm.

to simply calculate the daily duration and convexity return as $-5 \times (-10) = +50$ bp and $0.5 \times (-2/100) \times (-10)^2 = -1$ bp, respectively, and just aggregate over 10 days to get +500 bp duration return and –10 bp convexity return, for a total return of +490 bp. Instead, the daily duration drift of the portfolio due to falling interest rates must be estimated first. Using the definitions of duration and convexity, the duration change due to a change in interest rates can be estimated as:

$$\Delta OAD = (OAD^2 - 100 \cdot OAC) \cdot \Delta r / 10{,}000$$

where duration and convexity have the usual units and change of rates is measured in basis points. Due to the high convexity of the portfolio, over the course of the 10 days the duration of the portfolio shrinks by about 2 years. In addition, both the total return of the portfolio and the contributions of duration and convexity must be compounded daily (see Chapter 71 for details). After both adjustments, the total return calculation and breakdown are as follows:

Duration Return:	+408 bp
Convexity Return:	–10 bp
Total Return:	+398 bp

The total return is very close to the one estimated by analytics at the beginning of the period, but the breakdown between duration and convexity is dramatically different. In the daily model, the convexity contribution is much smaller than the duration contribution.

Daily attribution models typically use only the key-rate durations to explain the contribution of yield-curve changes. Any yield-curve change return (as estimated by the scenario-based total yield-curve change return) in excess of what can be explained by the key rates captures the contribution of the yield-curve movements between the key-rate points, as well as the convexity and other second-order terms and can be reported separately.

Implied Volatility Change Return

Securities with optionality require reference implied volatilities to calibrate the interest rate diffusion pricing model. In the fixed income world, most models use the Black swaption implied volatility surface[8] as input and calculate the sensitivity of the security value to the changes in implied volatility with a single analytic, Vega, which is the price change of the security for a 1% parallel shift in the Black implied volatility surface. Vega does not capture the effects of non-parallel

8. Swaptions are options on interest-rate swaps that are being priced using an extension of the classic Black-Scholes model, see Fischer Black and Myron Scholes, "The Pricing of Options and Corporate Liabilities," *Journal of Political Economy* 83 (1973), pp. 637-654. The volatility input in the Black-Scholes model that is consistent with the market price of such swaptions is commonly referred to as *Black volatility*. Swaptions are specified with two parameters, the tenor of the option and the maturity of the underlying swap. Therefore, the set of swaptions traded in the market is represented with a two-dimensional matrix, hence the term *volatility surface*.

movements of the implied volatility surface or the effect of yield-curve moves on the diffusion parameters of the interest-rate diffusion model.[9] Clearly, it does not sufficiently represent the sensitivity of the security value to changes in implied volatility surface. Some advanced models are capable of generating partial Vegas, e.g., sensitivities to exposures at multiple points of the volatility surface, or, alternatively, to a vector of parameters that can be used to parametrically fit the volatility surface. In such cases a more detailed decomposition of implied volatility change return is possible.

If only parallel Vega is available, capturing the total effect of implied volatility changes through scenarios is imperative. The scenario-based implied volatility change return can then be decomposed into a parallel shift component that is equal to the product of Vega and the average volatility shift, and a remainder that contains the effects of nonparallel volatility movements as well as the effects of changes of other inputs and parameters used in the volatility model.

Other Market Return

Although yield-curve and implied volatility are the most important factors in the pricing models of most fixed income instruments, they do not capture every aspect of the cash flows, and more factors may be required. Securities or derivatives with cash flows that depend on external factors, such as prepayments or inflation levels, may use additional inputs to the pricing model. Changes in such inputs will generate return that is not attributable to yield-curve or implied volatility surface changes. The effects of the changes of all others factors are captured together as Other Market Return.

For example, the model-projected cash flows of mortgage-backed securities may depend on market mortgage rates, as well as additional model-specific parameters such as home price appreciation expectations or swap spreads. All of these parameters contribute to Other Market Return. The breakdown to the various factors follows an instrument specific algorithm and depends on the availability of specific analytics.

Spread Change Return

The effect of OAS changes to return is captured in the spread change return component. Sensitivity to spread movements is measured directly using both spread duration (OASD) and spread convexity (OASC). The large spread moves often observed in the market make it necessary to use spread convexity. The difference

9. In the simple lognormal model, the stochastic component of the relative interest rate changes is proportional to a scalar, the log-normal (Black) volatility; therefore no dependence on interest rates exists. Other models that better capture the true behavior of interest rates make the stochastic term a function of black volatilities, as well as the level of interest rates or other model parameters.

between the sum of spread return captured by OASD and OASC and the scenario-based spread return contributes to the residual return component.

Reporting the return split of individual securities and sectors in a portfolio and a benchmark is very useful for the portfolio manager as it provides a detailed understanding of the sources of exposures and returns in the portfolio. When reporting return splits, attribution systems may re-organize the various components of returns. In particular, the Barclays Capital HPA model which we use for illustrations in this chapter, re-groups the return components along risk-factors as shown in Exhibit 70–2. Sample return splits for a few securities can be found in Exhibit 70–3.

OUTPERFORMANCE BREAKDOWN

Having split the returns in such detail based on analytical exposures to market factors, one might be tempted to proceed with bottom-up aggregation of outperformance per factor. However, neither does every portfolio manager use the factor approach to management, nor do all agree on which factors should represent portfolio risk. Many portfolios are managed by sectors or asset classes where top-down decomposition of outperformance is more appropriate, as the returns of the portfolio and the benchmark in each asset class or sector may differ. A flexible hybrid approach for performance attribution can be useful for both methods by allowing users to flexibly split total return into two parts: that driven by common factors for the entire portfolio and that in excess of common factors, which is further explained by asset allocation/security selection based on a user-defined hierarchical partition of the investment universe into sub-universes that we will refer to with the term "partition buckets."

Common components are explained by bottom-up aggregation as the difference of the exposure of the portfolio and the benchmark multiplied by the factor return. For example, yield-curve exposure is captured by duration, thus the outperformance explained by yield-curve movement would be the duration overweight of the portfolio (over the benchmark) multiplied by the negative of the yield-curve change. Excess of common or allocated components is explained by top-down decomposition using a user-defined hierarchical partition and the recursive algorithm discussed in Chapter 69, as will be detailed below.

This approach has the ability to accommodate different portfolio management styles. It also allows users to compare different ways of analyzing returns and outperformance and can lead to a better understanding of what drives portfolio outperformance. For example, many high-yield managers do not like to split total return into yield-curve, implied volatility and spread components, citing the high negative correlation between yield-curve and implied volatility return versus spread return. Instead, they prefer to manage total return as a whole. And even when they do wish to separate out yield-curve return and manage the excess-to-yield-curve return, they usually do not rely on spread duration and spread convexity to measure their exposure. However, when spreads were very tight in 2005, many high-yield managers began experimenting with spread duration-based management.

While any return split component could be considered as a bottom-up common return component or as an excess return component that participates in the top-down allocation algorithm, the following three common configurations support most portfolio management decision-making structures: Total Return Model, Excess Return Model, and Fully Analytical Model.

The *Total Return Model* is the simplest model, where the total return is considered a single allocated factor. In other words, there is no common factor, and the total return is explained by top-down decomposition using market value weights and a user-defined security partition.

The *Excess Return Model* takes advantage of the return splitting algorithm to separate the factors contributing to return into common and allocated factors.

Returns from common factors are explained by bottom-up aggregation using appropriate analytic weights (e.g., OAD, Vega, market beta, and the like.). For fixed income portfolios yield-curve and/or implied volatility are typically considered as common factors. Returns from other factors (excess-over-common factor returns) are explained by top-down decomposition as in the Total Return Model.

The *Fully Analytical Model* is the most detailed model. It takes full advantage of the return splitting algorithm and the hybrid allocation algorithm, where each factor can be explained either by the top-down or the bottom-up aggregation using appropriate weights.

The following sections discuss these different types of models in more detail.

TOTAL RETURN MODEL

The Total Return model is the most basic performance attribution model and follows the classical, sector-based, asset allocation/security selection framework. It is appropriate for portfolios whose managers make decisions solely based on the total returns of the securities. A typical usage is a portfolio whose managers are allocating the capital based on their views of the sector and security returns, rather than risk factors. The model is generic in that the allocation buckets can be defined via a user-defined partition using any of the hundreds of security attributes available. Allocations such as geography, size, and momentum can be used, essentially mimicking factor-based allocation. The partition should be defined to mimic the management structure of the portfolio.

The Total Return model uses the relative allocation method of the top-down decomposition algorithm as explained in Chapter 69, where sector market value weight w_s is the allocation weight $\alpha_{k,s}$, total return of sector s is the only factor return $f_{k,s}$, and total return of the benchmark is the hurdle rate.

Asset Allocation
$$w^P \cdot \sum_s \left(\frac{w_s^P}{w^P} - \frac{w_s^B}{w^B} \right) \cdot \left(TR_s^B - TR^B \right) \tag{70–1}$$

Sector Management
$$\sum_s w_s^P \cdot \left(TR_s^P - TR_s^B \right) \tag{70–2}$$

Top-Level Exposure
$$(w^P - w^B) \cdot TR^B \tag{70–3}$$

Absent leverage, the top-level weights of the portfolio and the benchmark are both equal to one, so the top-level exposure term is always zero.

Let us now re-visit the attribution example of the Chapter 69 to illustrate how results change according to the attribution model used. We remind the reader that in Chapter 69 we analyzed the outperformance of a multi-currency portfolio versus the Barclays Capital Global Aggregate G4 Index over a period of one month.

Here, we will focus only on the U.S. Dollar portion of the portfolio which achieved a +32.1 bp outperformance[10] versus the U.S. Dollar portion of the index.

Using the Total Return model and assuming that the asset allocation universe consists of the major asset classes in the U.S. Dollar fixed income markets, the total portfolio outperformance is split into +18.9 bp of asset allocation and +13.2 bp of security selection as shown in Exhibit 70–4.

The contribution of each asset class to both asset allocation and security selection is calculated based on the total return of each asset class in the portfolio and the benchmark using Eqs. (70–1) and (70–2) and reported in Exhibit 70–5.

The corporate sector contributes +7.4 bp to the outperformance, since it has been overweighted by about 10.9% (portfolio average weight: 30.7%, benchmark average weight: 19.8%) and its performance in the benchmark (+196.1 bp) is much higher than the performance of the benchmark itself (+129.8 bp). The approximate[11] calculation yields 10.9% × (196.1 – 129.8) = +7.2 bp, close to the +7.4 bp reported. The contribution to security selection is also shown and captures the performance advantage of the portfolio versus the benchmark, weighted by the portfolio weight of each sector. For the corporate sector, this calculation yields 30.7% × (107.9 – 196.1) = –27.1 bp, close to the –27.3 bp reported.

The analysis above assumed that asset allocation occurs only at the major asset class level (Treasuries, Government-Related, Corporates, Securitized, and Cash). It is likely that within each major asset class a second level of allocation to asset class subsectors will occur. For example, within the Securitized sector further allocation to the Residential Mortgages (RMBS) sector, the Commercial

Outperformance (bps)	**32.1**		

Source: Barclays Capital POINT

10. This number can be approximated from the reported numbers in Exhibit 69–6 of Chapter 69 as the ratio of the outperformance contribution of the U.S. Dollar portfolio (+14.6 bp) divided by the U.S. Dollar portfolio weight (45.5%). The calculation is not exact because the weight of the dollar portfolio fluctuates over the monthly attribution period.
11. The calculation is approximate because the algorithm used by the Barclays Capital HPA model that generated this report employs daily compounding. This calculation would be exact for single-day results.

Mortgages (CMBS) sector, the Asset-Backed (ABS) sector, and Covered Bonds may be desirable. As discussed in Chapter 69, a flexible attribution algorithm should support multiple decision levels. In our example, we introduce a second level of asset allocation by using asset class subsectors as defined by the Barclays Capital Global Aggregate Index classification scheme. In this case the Total Return model applied recursively reports a dramatically different breakdown between asset allocation and security selection as reported in Exhibit 70–6. Asset allocation shrinks from +18.9 bp to +2.9 bp, while security selection grows from +13.2 bp to +29.2 bp.

Intuitively, the finer the partition used for asset allocation the more emphasis is put on asset allocation decisions versus security selection decisions. In the limit, if the buckets of the asset allocation partition are individual securities, then the entire outperformance is reported as asset allocation. Conversly, if the asset allocation partition contains only one bucket, the entire outperformance is reported as security selection. Notice though that the transition between the two limits is not monotonic since individual partition buckets may contribute positively or negatively to both asset allocation and security selection. Such flexibility to define the asset allocation levels used in the breakdown of total outperformance is an important characteristic of an attribution system as it can support multiple styles of portfolio management. It is important that the partition used for performance attribution corresponds to the decision structure used for the management of a particular portfolio.

To understand the differences between single-level and two-level asset allocation, examine the two-level asset allocation details shown in Exhibit 70-7. In the Level-1 report, there are two columns for asset allocation, a top-level one (labeled simply Asset Allocation) which is identical to the asset allocation from the simple partition (+18.9 bp) and a Further Allocation column that captures subsequent allocation decisions (–16.0 bp). Their sum is +2.9 bp, the asset allocation reported in the summary report. Level-2 reports illustrate the details of the asset allocation into subsectors within each of the major asset classes. Asset classes for which no subsectors are defined (such as Treasuries and Cash) do not get Level-2 reports and do not contribute to Further Allocation.

Source: Barclays Capital POINT

Let us focus again on the corporate sector which shows –8.6 bp of underperformance contribution from Further Allocation. Its Level-2 decomposition table explains why: the portfolio had a large overweight to financial institutions, an underweight to industrials and no allocation to utilities. While both industrials and utilities outperformed the corporate benchmark, financials had a lower performance of +157.0 bp than the +196.1 bp of the aggregate corporate sector. Therefore, all three sectors have negative contribution to outperformance, with the largest (–5.1 bp) coming from financial institutions. Once again, this can be approximated with the recursive application of Eq. (70–1) as follows: 30.7% × (80.4% – 38.5%) × (157.0 – 196.1) = –5.0 bp close to the –5.1 bp reported. The security selection numbers represent security selection within each sub-sector.

EXCESS RETURN MODEL

The Excess Return model uses the return splitting algorithm to extract common factor returns from the total return and considers the remainder as excess return. In the fixed income world, portfolio managers like to manage their exposures to common factors such as the movement of the yield-curve and implied volatility surface separately from their other investment decision choices. For example, consider a manager who chooses to hedge the overall exposure to the yield-curve and makes investment decisions purely based on expectations of excess-to-curve returns. In this case, she would like to see the total outperformance breakdown into yield-curve and excess return so that she can assess the effectiveness of the hedge, as well as the asset allocation/security selection choices separately.

The outperformance due to exposure to common factors, which we will discuss in detail below, is explained by bottom-up aggregation. The excess return outperformance is explained by top-down decomposition using the relative allocation model of the Chapter 69, with sector excess returns and sector market value weights as in the Total Return model.

Asset Allocation
$$w^P \cdot \sum_s \left(\frac{w_s^P}{w^P} - \frac{w_s^B}{w^B} \right) \cdot \left(ER_s^B - ER^B \right) \tag{70–4}$$

Sector Management
$$\sum_s w_s^P \cdot \left(ER_s^P - ER_s^B \right) \tag{70–5}$$

Top-Level Exposure
$$(w^P - w^B) \cdot ER^B \tag{70–6}$$

Once again, if neither the portfolio nor the benchmark is leveraged, the top-level weights are equal to one and the top-level exposure term is equal to zero.

Exhibit 70–8 shows the outperformance breakdown when using the Excess Return model and the two-level asset allocation in the previous example. The left-hand side table shows the results when only interest rates are treated as common return factors. Most of the outperformance (+24.6 bp) comes from the yield-curve exposure. Asset allocation is responsible for –2.2 bp and security selection

EXHIBIT 70–8

Outperformance Breakdown Using the Excess Return Model

		Security Selection	9.6

Source: Barclays Capital POINT

for +9.7 bp. The right-hand side table shows the results when, in addition to interest rates, implied volatility is also treated as a common factor. The Implied Volatility term contributes +1.9 bp to outperformance, altering the asset allocation contribution to –4.0 bp and the security selection contribution to +9.6 bp.

Outperformance Due to Yield-Curve Exposure

As discussed at the beginning of this chapter, the pricing framework for most fixed income securities essentially amounts to projecting future cash flows and discounting them at projected paths of interest rates. Government, swap, or municipal AAA interest rate yield curves can be used as the reference yield-curve, depending on the type of the security.

The yield-curve contribution to outperformance includes yield-curve change, the effect of interest rate changes, and yield-curve carry, the effect of the change of yield-curve discount factors or interest rate-related projected cash flows with the passage of time assuming that rates stay unchanged. There exist two different philosophies with respect to the definition of what constitutes a change in interest rates, and they result in different breakdowns between yield-curve carry and yield-curve change; however, the total yield-curve effect (their sum) is identical under both methodologies.

Methodology I: Rolling on Forwards

A yield-curve is deemed unchanged if the rates realize the values implied by the forward rates in the previous period. For example, if we look at an unchanged yield-curve one month into the future, the 1-year rate is equal to the one month forward 1-year rate calculated from today's yield-curve. In this methodology, a yield-curve change is calculated with respect to the projected forward rates, and carry always accrues at the short rate.

This method is not very popular (particularly among cash investors) because it introduces significant complexity in the estimation of yield-curve change return—the most important component of fixed income returns. In addition, forward rates are not particularly good predictors of the realized path of interest rates, further reducing the appeal of this method.

Methodology II: Parallel Translation

A yield-curve is deemed unchanged if the level and shape of the yield-curve remains unchanged. For example, if we look at an unchanged yield-curve one month into the future, the 1-year rate is equal to the 1-year rate in today's yield-curve. In this methodology, a yield-curve change is calculated with respect to today's yield-curve, and carry accrues at a different rate for each cash-flow.

Further, the representation of the yield-curve (e.g., par rates, zero rates, forward rates) is important and affects the breakdown of total yield-curve return between carry and change. If instantaneous forward rates are used to represent the yield-curve, then each cash-flow accrues carry at a rate equal to the forward rate corresponding to the cash-flow date. Securities with deterministic cash flows accrue carry at a rate equal to the average of the forward rates corresponding to the date of each cash-flow, weighted by the present value of each cash-flow. Unfortunately, the forward rate representation is not very popular since forward rates are not directly observable in the market. Investors prefer the better understood zero or par rates to represent a yield-curve. Under both representations, the calculation of the curve carry of a set of cash flows is complicated. From the discussion above it is evident that the breakdown of yield-curve return and outperformance into curve carry and curve change is somewhat subjective. Portfolio managers should have the flexibility to choose a methodology which is consistent with their style of management.

Since interest rate yield curves are infinite-dimension objects, we need to represent them with a finite set of parameters. The simplest method is to choose a small discrete set of yield-curve points (key-rate points) dispersed along the yield-curve. The premise is that the dynamics of the yield-curve can be represented with the dynamics of the key rates with a high degree of accuracy. Intermediate yield-curve points are assumed to move as a linear combination of the moves of adjacent key rates. A typical set of key rates used includes the 6-month, 2-year, 5-year, 10-year, 20-year and 30-year points for most currencies. Other curve points that also appear are the 1-month, 3-month, 1-year, 3-year, 7-year, 12-year, 15-year, 25-year and 40-year points. Some managers prefer to represent the curve using factors that are defined as linear combinations of curve points. The prototype for such representation is the level-slope-butterfly set of factors, a representation implied by the principal component analysis of yield curves. The choice of yield-curve representation depends on the type of yield-curve exposure a portfolio is taking as well as the capabilities of the underlying analytics system.

Although the key rates or level-slope-butterfly representation of the yield-curve is highly accurate from a risk perspective (captures more than 99% of its

variance), there may be deviations from a return perspective, especially if a small number of points are used. Indeed, there are periods where, for example, the three-year U.S, Treasury rate moves very differently than what is implied from the two-year and five-year rates. Analytics (key-rate durations) explain the bulk of yield-curve outperformance. Scenario-based outperformance calculations are used to capture any residual outperformance from intermediate yield-curve points and convexity.

Yield-Curve Carry

As discussed above, yield-curve carry calculations are complex even for bullet securities under par- or zero-rate representation of yield curves. An approximation method for the calculation of yield-curve carry, called the Curve Matching Portfolio (CMP) method, can be used to simplify these calculations.

The basic idea is to define a set of par and/or zero-coupon reference bonds whose yield-curve carry can be easily computed analytically, and then construct a carry-matching portfolio of such bonds for each portfolio or benchmark security. The matching algorithm attempts to create a portfolio that earns the same yield-curve carry as the security.

Matching par bonds are made to have a coupon equal to the par key rate of the corresponding maturity and a price of par (100). The payment frequency and day count convention match those used for yield-curve construction. As a result, all matching par bonds on the day of construction have an option-adjusted spread of zero by construction. Zero-coupon bonds do not pay coupons, but have yields matching the zero rates for maturities matching each point.

A curve matching portfolio consisting of reference bonds and cash is created for each security in the portfolio and benchmark such that the cash-flow profile of the portfolio matches the one for the bond. Since dealing with bond cash flows (which are often nondeterministic) is generally difficult, some algorithms use key-rate durations to represent the concentration of cash flows around each key-rate point. Therefore matching the key-rate durations of the curve-matching portfolio and the bond is an approximate way to match their cash-flow profiles and thus the curve carry. Cash is added or subtracted from the matching portfolio to make sure that it has the same present value with the bond. The amount of cash needed to replicate any particular bond can vary according to the duration profile and price of the bond. For example, if only par bonds are used in the matching portfolio of a bond with a higher coupon than the current par rate, leverage must be used in the matching portfolio (borrowing at the short rate to fund the future cash flows) to match the cash-flow profile of the bond. This leads to a negative amount of cash in the matching portfolio.

A common choice for the set of matching reference bonds is to use one par or zero bond per key-rate point. The weights of each reference bond (and cash) are aggregated over all positions in the portfolio and benchmark. Let us represent with ω_j^P and ω_j^B weights allocated to reference bond and cash in the curve-matching portfolio of the portfolio and benchmark respectively, with j spanning

all key-rate points and cash. If we approximate the carry return of each reference bond and cash as its yield (by definition the corresponding key rate level) multiplied by the attribution period length $y_j \Delta t$, the yield-curve carry outperformance can be broken down per key-rate point contribution as $\sum_j \left(\omega_j^P - \omega_j^B\right) \cdot y_j \cdot \Delta t$. If we define the average portfolio or benchmark yield as the average of all key rates using the CMP portfolio weights, the above formula can be re-written as $\left(y_{avg}^P - y_{avg}^B\right) \cdot \Delta t$. The excess yield-curve carry contribution of each key rate over the average carry can be defined, but the sum over all key rates will be zero.

Generally, yield-curve carry can be broken down using the following equations:

Outperformance from average carry $$\left(y_{avg}^P - y_{avg}^B\right) \cdot \Delta t \tag{70–7}$$

Key rate contributions $$\sum_j \left(\omega_j^P \left(y_j - y_{avg}^P\right) - \omega_j^B \left(y_j - y_{avg}^B\right)\right) \cdot \Delta t \tag{70–8}$$

If the average yield is set to zero for both portfolio and benchmark, then the average carry term is zero and the yield-curve carry outperformance is attributed to each key rate. If the average yield is calculated using the CMP weights for portfolio and benchmark, then the average carry is equal to the total carry contribution and the sum of the excess key rate contributions is equal to zero. Other choices for the average yield are also possible.

Yield-Curve Change

Yield-curve change outperformance is a result of duration profile differences between the portfolio and the benchmark and the change in the yield-curve. The scenario-based return decomposition described earlier is used to compute the total yield-curve change return and hence the outperformance. Then, by using the analytics (OAD and KRDs), the total yield-curve change outperformance is decomposed further into a parallel shift component, a curve reshaping (at the key-rate points) component, the rest of yield-curve contribution and the effects of convexity.

The outperformance from parallel yield-curve shift is computed by applying the bottom-up aggregation, using key-rate durations as loadings and key rate changes as factors. Similar to yield-curve carry, the notion of an average yield change (parallel shift) can be used to control how the yield-curve change outperformance is distributed between the key rate contributions and the parallel shift term.

Outperformance from avg. parallel shifts $$-(OAD^P - OAD^B) \cdot \Delta y_{avg} \tag{70–9}$$

Outperformance from reshaping $$-\sum_j \left(KRD_j^P - KRD_j^B\right) \cdot (\Delta y_j - \Delta y_{avg}) \tag{70–10}$$

If the average yield change is set to zero, the yield-curve change outperformance will be attributed to each key rate separately. If the average yield change is set equal to an appropriately defined parallel shift, the key rate terms capture the outperformance in excess of the parallel shift; i.e., the yield-curve reshaping effect on outperformance.

Since we represent the shape of the yield-curve by key-rate points, there will always be a small fraction of yield-curve change outperformance not captured by the above methodology, as explained at the beginning of this section. Exhibit 70–9 illustrates the change not captured by the key rates.

This final piece of the yield-curve change outperformance, calculated as the difference between total yield-curve change return from the scenario-based decomposition and the sum of the average parallel shift and reshaping return, includes the change in excess of key rates as well as return from convexity and other higher-order terms.

Exhibit 70–10 displays a yield-curve attribution report as produced by the Barclays Capital HPA model.[12] The total yield-curve outperformance of +77.4 bp is broken into +2.9 bp of curve carry and +74.4 bp of curve change. Each is further broken down into an average curve contribution, the excess-to-average contributions of each key-rate point and the rest of the curve and convexity effect. The key rate levels and their changes over the attribution period (one month in this example) as well as the portfolio exposures in terms of curve matching portfolio weights and key-rate durations are displayed to help users better understand the reported outperformance breakdown.

To illustrate how this can be done we will focus on curve carry. The average yield of the portfolio and the benchmark are calculated as the yield of the corresponding yield-curve–matching portfolios. Since the portfolio is longer than the benchmark (as indicated by its higher duration) in an upward sloping yield-curve, its average yield is higher than the benchmark (2.030% versus 1.698%).

Source: Barclays Capital POINT

The corresponding average yield-curve carry contribution can be approximated[13] using Eq. (70–7) as the excess yield of the portfolio times the elapsed time of one month, (2.030% – 1.698%) × (1/12) = +2.8 bp, close to the +2.9 bp shown. The additional contributions of key-rate points can be estimated using Eq. (70–8). For example, the 2-year point contributes approximately [39.5% × (0.771% – 2.030%) – 37.4% × (0.771% – 1.698%)] × (1/12) = –1.3 bp, close to the –1.4 bp shown.

Outperformance Due to Implied Volatility Exposure

For fixed income securities with optionality, pricing models are typically calibrated to reflect the Black swaption implied volatility surface prevailing in the market. Therefore, changes in implied volatility create returns on the embedded option that must be attributed correctly in performance attribution. Similar to how the contribution of yield-curve changes are measured, both scenario- and analytics-based calculations are used to break down the contribution of implied volatility changes to outperformance. The outperformance due to exposure to implied volatility is typically calculated in terms of volatility decay, parallel shift of the implied volatility surface, and surface reshaping.

Volatility Decay

Volatility decay captures the change in option value due to the lapse of time. The return from volatility decay is difficult to capture exactly, as it requires re-simulating interest rate paths and pricing securities using two separate time variables (one for diffusion and the other for discounting). However, volatility decay return can be approximated by subtracting all other components of the total time return, such as yield-curve and spread carry. Outperformance due to volatility decay is the difference between the weighted average volatility decay return of the portfolio and the benchmark.

Implied Volatility Change

The outperformance due to implied volatility change is a result of the difference in volatility exposures of the portfolio and the benchmark and the change in the implied volatility surface. The exposure to parallel shift is measured by Vega, and the parallel shift return is equal to Vega multiplied by the average implied volatility change over the entire surface. The implied volatility surface reshaping return, as well as additional terms that represent other parameters entering the fitting of the implied volatility surface can be calculated as the scenario-based total implied volatility return minus the return from the parallel shift.

Exhibit 70–11 shows a sample implied volatility report[14] produced by the Barclays Capital HPA model. Volatility outperformance is broken down into the contributions of the major asset classes in the portfolio and benchmark.

13. Remember that these formulas hold for attribution over a single period while the example goes over a month using a daily compounding attribution algorithm.
14. The portfolio and benchmark in this report are the U.S. dollar portions of the global portfolio used in the example of Chapter 69.

Source: Barclays Capital POINT

The report contains the initial implied volatility level and its change over the attribution period for each asset class.[15] In this example, implied volatility exposure occurs only in the government-related, corporate, and securitized sectors. The ability of an issuer to call a bond and the prepayment option of mortgage-backed securities give issuers of such bonds optionality, therefore long exposure to implied volatility. Conversely, holders of such bonds are short volatility, as the negative exposure numbers indicate. By being long the corporate and short the securitized sector, the portfolio is implicitly underweighted volatility in the corporate sector and overweighted volatility in the securitized. Since on average implied volatilities increased 5.71% during this month, the corporate sector contributes negatively to parallel volatility outperformance (–0.6 bp), and the securitized sector contributes positively (+6.6 bp). Overall, the portfolio is long volatility since the volatility exposure of the securitized sector is much bigger than that of the corporate and government-related sectors. The total parallel volatility change outperformance contribution is +6.2 bp. The total contribution of changes in the implied volatility surface is calculated from the return splits scenarios, as described above. From that, the surface reshaping (net of the parallel shift) contribution as well as the effects of other parameters and factor of the volatility model are calculated as –3.8 bp. Finally, a net long volatility portfolio will suffer loss of return because of volatility decay. In this case, it has been calculated to be –0.5 bp. Putting it all together, the total contribution of implied volatility to the outperformance of the dollar portfolio is calculated to be +1.9 bp.

FULLY ANALYTICAL MODEL

The Fully Analytical model offers the flexibility to match the increasing diversity in portfolio management structures. It takes full advantage of the return splits by isolating returns from each factor individually. The model can accommodate either bottom-up aggregation or top-down decomposition, depending on how the factor exposures are managed in the portfolio. It is suitable for portfolios with multiple asset classes, as they often have exposures to different market risk factors. For example, consider a portfolio consisting of corporate bonds, mortgage-backed securities and inflation-linked bonds. While all of these securities are exposed to changes in interest rates and possibly implied volatility, mortgage securities have additional exposure to prepayment risk and mortgage spreads, and inflation-linked securities have additional exposure to their reference

15. Although in this report the average volatility of each bucket is reported to be the same, generally each security is exposed to different points of the volatility surface. It is difficult to estimate a single point representing the reference point for each security hence this report is using the simplistic approach where all securities are exposed to the same point for parallel shift calculations. Since the total effect of implied volatility changes is captured using scenario-based returns breakdown this choice only affects the breakdown between the average volatility change and the reshaping components.

inflation indices. Similar to how the yield-curve risk is managed, managers of mortgage and inflation-linked securities tend to manage these additional risk factors separately. The ability to break down outperformance due to specific factor exposure can be very valuable to the managers for explaining the impact of their portfolio decisions.

Furthermore, the Fully Analytical model allows portfolio managers to use measures other than market value as allocation weight. This is particularly useful for managers who allocate their capital to various sectors based on risk exposures rather than market values. For instance, a manager taking views on sector spread movement may think of over/underweight in terms of option-adjusted spread duration (OASD). In the credit space, the concept of duration-times-spread (DTS) has been gaining traction in recent years as an alternative measure of spread risk exposure.[16] As a result, credit portfolio managers may prefer to use OASD or DTS as allocation weight in performance attribution.

For illustrative purposes here, we will use the Fully Analytical model with the following choices: Yield-curve and implied volatility are considered common factors and their outperformance contribution is explained using bottom-up aggregation as previously described. The outperformance from mortgage and inflation factors as well as residuals are also explained using bottom-up aggregation and the details of their decomposition is described in the following sections. These factors are calculated per security and can be aggregated to buckets of the selected partition. Outperformance from spread is calculated in a top-down fashion using analytics-based exposure weights for spread change outperformance but market value weights for spread carry outperformance, as described in detail below.

Outperformance Due to Spread

Outperformance from spread is explained using top-down decomposition into asset allocation and security selection per user-defined hierarchical partition or sector. All three components of spread outperformance (carry, spread duration, and spread convexity) are decomposed separately using the top-down decomposition algorithm. Spread carry outperformance is decomposed by applying the absolute allocation algorithm using market value weights and carry returns. We consider two different methods for the decomposition of the spread change outperformance: top-level and sector-level.

Top-Level Spread Model

The top-level spread model assumes that there is a decision to over/underweight the spread duration exposure of the portfolio against the benchmark at the portfolio

16. See Arik Ben Dor, Lev Dynkin, Patrick Houweling, Jay Hyman, Erik van Leeuwen, and Olaf Penninga, *A New Measure of Spread Exposure in Credit Portfolios* (Barclays Capital Publications, February 2010).

level (top level). Subsequent decisions to allocate spread duration exposure to various sectors are made relative to the portfolio spread duration. This implies that allocation weight is measured by the ratio of the spread duration contribution of each sector ($w_s OASD_s$) over the portfolio spread duration. In other words, we apply the relative allocation method of the top-down algorithm of the Chapter 69 using $\alpha_k \leftarrow OASD$, $\alpha_{k,s} \leftarrow w_s OASD_s$, $f_{k,s} \leftarrow -\Delta OAS_s$ and $-\Delta OAS^B$ as hurdle rate.

Asset Allocation $$-OASD^P \cdot \sum_s \left(\frac{w_s^P OASD_s^P}{OASD^P} - \frac{w_s^B OASD_s^B}{OASD^B} \right) \cdot \left(\Delta OAS_s^B - \Delta OAS^B \right) \quad (70\text{–}11)$$

Security Selection $$-\sum_s w_s^P OASD_s^P \cdot \left(\Delta OAS_s^P - \Delta OAS_s^B \right) \quad (70\text{–}12)$$

Spread Duration Mismatch $$-(OASD^P - OASD^B) \cdot \Delta OAS^B \quad (70\text{–}13)$$

Here, the Top-Level Exposure term has been renamed Spread Duration Mismatch.

Sector-Level Spread Model

In contrast to the top-level model, the sector-level model assumes no such spread duration decision at the portfolio level. Instead, each asset allocation decision is made without any top-level restriction. In this case, the appropriate allocation weight is the absolute, rather than relative, spread duration contribution. Furthermore, the hurdle rate is set to zero, as sector views are expressed on the absolute (rather than relative) changes in sector spreads. In other words, the absolute top-down decomposition is applied using $\alpha_{k,s} \leftarrow w_s OASD_s$ and $f_{k,s} \leftarrow -\Delta OAS_s$.

Asset Allocation $$-\sum_s \left(w_s^P OASD_s^P - w_s^B OASD_s^B \right) \cdot \Delta OAS_s^B \quad (70\text{–}14)$$

Security Selection $$-\sum_s w_s^P OASD_s^P \cdot \left(\Delta OAS_s^P - \Delta OAS_s^B \right) \quad (70\text{–}15)$$

Exhibit 70–12 shows the USD Local Management outperformance decomposition of the US Dollar portfolio discussed earlier in this chapter using the Fully Analytical model with either top-level or sector-level spread duration management. We assume two-level allocation of spread exposure, first to major asset classes and then to subsectors of each asset class. In both models a new category, Mortgage,[17] has appeared and is responsible for –8.2 bp of outperformance. In both models, the security selection contribution is +9.3 bp. The difference comes from the treatment of spread duration exposure. The top-level model treats it as a portfolio-level decision (essentially a common return factor) contributing –1.8 bp of outperformance under the label Spread Duration Mismatch, while asset allocation is listed as +5.0 bp. The sector-level model makes spread duration exposure

17. We will discuss this term in more detail below.

part of the allocation decision and essentially combines the two terms, reporting asset allocation of +3.2 bp.

Exhibit 70–13 contains the Asset Allocation report to major asset classes (first level of allocation) using the sector-level model. Outperformance from asset allocation and security selection from each partition bucket is displayed, along with other useful information such as OAS and the changes in OAS, OASD, OASC, and market value weights.

The asset classes with the biggest contribution to spread change asset allocation outperformance are securitized with +4.4 bp and corporate with –1.7 bp. These numbers can be explained as follows. The securitized sector has an underweight of –0.3 years in terms of spread duration (0.8 years versus 1.1 years as seen in the top panel), while benchmark spreads in this sector widened 15.9 bp. Note that since we use the sector-level model, the hurdle rate is zero; therefore, we do not need to compare the spread widening of each sector with that of the benchmark. The approximate calculation estimates the contribution as –0.3 × –15.9 = +4.8 bp, relatively close to the +4.4 bp shown.

Spread carry contributes +1.5 bp to asset allocation, coming mostly from the corporate sector, which has high spread (+186.5 bp versus +57.1 bp for the benchmark) and is market value overweighted (30.7% versus 19.8%). The approximate calculation is (30.7% – 19.8%) × (186.5 – 57.1) × (1/12) = +1.2 bp.

EXHIBIT 70–12

Outperformance Breakdown Using the Fully Analytical Model

Fully Analytical Model (Top-Level)		Fully Analytical Model (Sector-Level)	
Outperformance Details		**Outperformance Details**	
Yield-Curve	24.6	Yield-Curve	24.6
Implied Volatility	1.9	Implied Volatility	1.9
Asset Allocation	5.0	Asset Allocation	3.2
Security Selection	9.3	Security Selection	9.3
Spread Duration Mismatch	–1.8	Mortgage	–8.2
Mortgage	–8.2	Residual	1.3
Residual	1.3		

Source: Barclays Capital POINT

Columns for further allocation[18] representing the contribution of spread exposure allocation to subsectors are also included.

Exhibit 70–13 also provides information to confirm the USD spread duration mismatch term from the top-level model (Exhibit 70–12, left panel). Indeed, the portfolio is slightly longer than the benchmark in terms of spread duration (4.7 versus 4.5 years), and benchmark spreads widened by 8.3 bp on average. Multiplying the spread overweight by the negative of the benchmark spread change yields $+0.2 \times (-8.3) = -1.7$ bp close to the –1.8 bp shown in Exhibit 70–12.

Mortgage Factors

The present value of mortgage-related securities depends on additional factors such as prepayments and mortgage rates. Some common additional factors are described below.

Prepayment Surprise Outperformance

Securities involving prepayments are priced using model predictions of future cash flows. Over a month, the realized prepayment rate is generally different from the one predicted by the model. The difference gives rise to a return component that is not captured by analytics; this return can be computed separately as Prepayment Surprise return. In the Barclays Capital Global Aggregate G4 index which is the benchmark in this example, prepayments are recognized on the first of the month based on a predicted rate (which, if different from the model-predicted one, will generate surprise return). Over the course of the month, the actual prepayment rate can be more accurately predicted and used to adjust the returns, leading to more days where the surprise return is non-zero. Once the actual rate is known and returns are adjusted to reflect it, no more surprise return for that particular month will occur. Note that portfolio accounting conventions with respect to recognizing realized prepayments may vary. If they are different from the benchmark conventions, the attribution system will report prepayment surprise outperformance that is not economic but accounting in nature.

Mortgage Spread Change Return

A common factor that affects the cash flows of all mortgage securities is the difference between the model-implied mortgage rate and the actual mortgage rate observed in the market. This difference is called the mortgage spread and the

18. It is interesting to note that further allocation must use the relative spread duration allocation model, since the spread duration of each major asset class has been determined at the first level of allocation. The spread duration allocation to subsectors must be consistent with the pre-determined spread duration of the asset class.

price sensitivity of a security to this spread is the mortgage spread duration. The return due to mortgage spread change is usually estimated with a first order approximation as the product of the mortgage spread duration and the negative of the change in the mortgage spread, i.e., $-MtgRtDur \cdot \Delta MtgSpread$. The outperformance is the difference between the weighted average mortgage spread return of the portfolio and the benchmark.

Other Mortgage Factors

A number of other parameters such as home price appreciation projections and swap spreads may also be used in mortgage pricing models. In the scenario-based return splits, all such parameters are accounted for in Other Market Return scenario. For mortgage securities, the difference between the other market return and the mortgage spread return captures the return from factors for which no analytics are available. If this difference is significant, it is an indication that additional analytics are required to better understand the sources of risk and performance of mortgage securities under the particular valuation model.

Exhibit 70–14 displays a portion of a detailed position-level outperformance contribution report for the US Dollar portfolio discussed earlier in this chapter. The contribution of each position is broken down per factor. Outperformance components that are allocated in a top-down fashion such as spread carry and spread change are listed under "Security Selection." Components aggregated in a bottom-up fashion such as mortgage factors and residual are listed under "Other." Exhibit 70–14 is focused on the securitized sector, which is solely responsible for the –8.2 bp of underperformance attributable to mortgage factors. This report can be very useful to help managers drill down to the position level and understand the drivers of outperformance per individual factor.

Inflation Factors

Inflation-linked securities have cash flows linked to a specified price index. For example, the principal and interest payment of U.S. Government Inflation-Linked bonds (TIPS) are linked to the Consumer Price Index for All Urban Consumers (CPI-U), non–seasonally adjusted. The value and the return of inflation-linked securities depend on realized inflation as well as on expectations of future inflation during the lifetime of the security.

The analysis of the risk and performance of inflation-linked securities is subject to debate. One school of thought prefers to treat them as independent of nominal interest rates and express risk and performance as a function of real rates (nominal rates minus inflation expectations). In this type of analysis, the return of inflation-linked securities comes from changes of real rates, as well as time return, which is a combination of real rate carry and realized inflation accretion.

Another school of thought prefers to decompose real rates into the difference of nominal interest rates and inflation expectations such that nominal interest rate risk and contribution to outperformance is accounted consistently across

EXHIBIT 70–14

all types of bonds. The numbers shown below are calculated following the latter approach.[19] Inflation expectations are captured by a negative discounting spread (similar to OAS), which is called inflation spread. The return of inflation-linked securities is explained by changes in nominal interest rates and inflation spreads. The time return is captured by the nominal interest rate carry reduced by the negative inflation spread carry and increased by realized inflation accretion. Since realized inflation is announced only once a month, an assumption about the projected inflation of the current month is required to ensure smooth daily inflation accretion. When realized inflation is announced, it is generally different from projected inflation, producing a return that cannot be otherwise accounted for. This kind of return of inflation-linked securities is called inflation surprise and is accounted separately. Inflation surprise return is also present when current month inflation projections change.

Exhibit 70–15 shows the Fully Analytical model's security return splits for the Barclays Capital Inflation Linked US TIPS index for the period from July 16, 2010 to August 13, 2010. These dates correspond to the CPI-U announcement dates for the index level as of the end of June and July, respectively; therefore, the index should show a realized inflation return equal to the rate of inflation realized during July (but only becoming known on August 13).

The total return of the index was +169.9 bp, with the majority coming from nominal interest rates exposure (+27.7 bp carry and +184.6 bp of yield-curve change). Inflation related return was negative at –40.6 bp, most of it coming from falling inflation expectations (captured under inflation spread change as –29.7 bp). Inflation accretion during July was –3.0 bp, indicating that at the beginning of the month, the market actually expected a small amount of deflation at an annualized rate of $-0.03\% \times 12 = -0.36\%$. The positive inflation surprise of +5.3 bp indicates that the realized inflation was actually positive, although quite low. The total realized inflation return is +2.3 bp, the sum of inflation accretion (at the market expected rate) and inflation surprise. From that, July realized annualized inflation can be calculated to be approximately $+0.023\% \times 12 = +0.28\%$. Indeed, the CPI reading for June was 217.965 and the one for July 218.011, implying an inflation rate for July of 218.011/217.965 –1= 2.11 bp or +0.25%. The inflation spread carry term of –13.1 bp reduces the yield-curve carry of +27.7 bp that was credited to the index due to exposure to nominal rates. The difference of the two can be thought of as the carry earned by the index due to exposure to real rates, i.e., nominal rates reduced by inflation expectations.

Another interesting thing to note is that inflation expectations did not fall uniformly across all maturities. Indeed, short bonds exhibited positive inflation spread return, indicating increasing inflation expectations over the next three years or so. This is also the case for very long bonds, with the 30 year bond showing increasing inflation expectations. Inflation expectations fell only for bonds

19. This approach is detailed in Anthony Lazanas and Jeremy Rosten, *Risk Modelling and Performance Attribution for Inflation-Linked Securities* (Lehman Brothers Publications, October 2005).

with maturities between 3.5 and 20 years. This indicates that inflation portfolio managers need to pay more attention to the term structure of expected inflation exposure and use more detailed analytics that provide partial sensitivities to the inflation term structure.

SELECTING AN APPROPRIATE ATTRIBUTION MODEL

From the above discussion, it should be clear that many variants of attribution models exist and that a portfolio manager must choose one that best corresponds to the decision structure during portfolio management. The results from several models applied to the U.S. dollar–denominated portion of the portfolio/benchmark from Chapter 69 are summarized in Exhibit 70–16. All models assume two-level asset allocation, first to major asset classes and then to subsectors of each asset class.

Essentially, models differ with respect to what factors of return are managed at the portfolio level via allocations of appropriate exposures (factor-based management) and which component of return is managed via allocation to sectors and security selection within each sector (sector-based management).

Each successive model brings one additional common factor. The Excess of Yield-Curve model introduces yield-curve exposure as a common factor; the Excess of Yield-Curve and Implied Volatility model introduces implied volatilities; the Fully Analytical model with sector-level allocation of spread exposure

EXHIBIT 70–16

Outperformance Contributions Using Various Models

	Total Return	Excess of Yield-Curve	Excess of Yield-Curve and Vol	Fully Analytical (Sector-Level)	Fully Analytical (Top-Level)
Total	32.1	32.1	32.1	32.1	32.1
Yield-Curve		24.6	24.6	24.6	24.6

introduces all other factors for which there exist explanatory analytics (mortgage factors only, in this particular portfolio) as well as residual; and the Fully Analytical model with top-level allocation of spread exposure introduces top-level spread duration as a common factor.

Flexibility is a very important feature of attribution algorithms. Portfolio management styles differ, and an attribution platform must have sufficient richness so that a model representing each management style can be chosen. In addition, running multiple versions of the performance attribution algorithm may help portfolio managers reveal exposures that they have been implicitly taking and help them improve their management process.

KEY POINTS

- The total return of a security can be broken down to the contributions of various risk factors such as yield curve, volatility, spread, mortgage, and inflation—based on the variables used in the pricing model for that security type.
- Various models can be applied to allocate these components of return in different ways to correspond to the management structure of a portfolio.
- The Total Return Model considers all return as a single allocated factor and divides the difference in performance versus a benchmark into allocation to sectors and sector performance using market value weightings.
- The Excess Return Model extracts common factors, such as yield-curve and volatility, and allocates outperformance from excess return using a top-down algorithm into asset allocation and security selection. Relative performance from common factors is determined using bottom-up aggregation.
- The Fully Analytical model allows any return split component to be extracted as a common factor for bottom-up aggregation. Alternative weights, such as spread duration, can be used in allocation calculations to provide a risk-weighted view.
- It is most effective to choose a primary performance attribution model that matches the management structure of the portfolio. This provides a more effective evaluation of the performance due to exposure to the factors used in the decision making process.

The principles of performance attribution are outlined in Chapter 69 and a detailed attribution analysis for fixed income portfolios is discussed in Chapter 70. This chapter explores topics that more complex portfolios or analysis may encounter in practice. In particular, we start looking at the attribution exercise in a multicurrency context. Given the fact that the majority of multicurrency portfolios have some type of foreign exchange (FX) hedging overlay, being able to accurately separate the performance due to active FX positions from that due to hedging is a complex but important exercise. Another important topic discussed in this chapter concerns the treatment of returns and outperformance due to the use of derivatives or leverage in the portfolio. Their presence may change the nature of the basis used to define returns, so we discuss in more detail how to change the analysis in order to maintain the integrity of the performance attribution. This chapter finishes with the discussion of other practical considerations that performance attribution exercises often encounter. These include issues such as multi-period compounding, transaction handling, and missing or incorrect input data.

MULTICURRENCY ATTRIBUTION

In Chapter 70, we used performance attribution to examine the portfolio at the local market level, that is, associated with a particular currency market. Multicurrency portfolios add an additional layer of complexity to the portfolio management structure. For instance, there may be decisions made at the global level to determine capital allocation across different local markets or the FX exposures to those markets. In this section, we describe in more detail how one can decompose total global outperformance in terms of FX allocation, local market allocation and local market management.

To study the FX component of the portfolio's return, we need to define first the base currency of analysis, the currency in which we define the portfolio's return. Note that by definition, securities denominated in the base currency do not have FX exposure or return.

FX Return Splitting

Since most portfolio managers prefer to manage FX risk separately from all other risk exposures, the first step in return splitting of non-base-currency-denominated securities is to separate the FX component of return from the local component of return. The base currency total return of security i ($^{b}R_i$) can be expressed in terms of its local currency return (R_i) and the spot FX return of the currency in which the security is denominated, F_i .[1]

$$^{b}R_i = F_i + R_i F_i + R_i \tag{71–1}$$

Here, we assume that all positions with cash flows or dependencies on interest rates in multiple currencies (such as FX swaps, FX forwards) have been decomposed into legs that have exposure only to the market parameters of a single currency. Note the presence of a cross-term that is the product of the FX return and the local currency return. This can be accounted separately, but in most cases it is combined with the FX return under the assumption that the FX return is typically much larger than local currency returns. While this is generally true for fixed income securities, it may not be true for portfolios that invest in asset classes with higher volatility, such as equities or commodities.

To separate the performance due to FX exposures from the performance due to local management, we need to include the cash deposit return of each currency in the FX return.[2] Indeed, a cash investment in any foreign currency will

1. This formula is applicable to fully funded securities only. When leverage is present, such as in derivatives, it needs to be adjusted appropriately.
2. Brian D. Singer, and Denis S. Karnosky, "The General Framework for Global Investment Management and Performance Attribution," *Journal of Portfolio Management* (Winter 1995), pp. 84–92.

earn the FX return plus the local cash deposit return over the attribution period, R_i^{depo}, without incurring any local risk.

$$^{b}R_i = \left(F_i + R_i^{depo}\right) + R_i F_i + \left(R_i - R_i^{depo}\right) \tag{71–2}$$

The total return of the portfolio can then be written as the sum of returns from "local markets" that correspond to the first allocation layer of a multicurrency portfolio. Although single-currency markets provide the natural breakdown for FX returns, there is no reason to impose the same breakdown for local returns. In fact many managers allocate local return exposure to markets based on geography, asset class, or industry, rather than currency. We will denote the local return allocation markets with m and we will generally assume that they are not necessarily single-currency markets. Single-currency markets will be denoted with c and will be used for the allocation of the FX component of return, as well as the cross term.

$$^{b}R^P = \sum_c {}^{b}w_c^P \cdot \left(F_c + R_c^{depo}\right) + \sum_c {}^{b}w_c^P R_c^P F_c + \sum_m {}^{b}w_m^P \cdot \left(R_m^P - R_m^{depo,P}\right) \tag{71–3}$$

The three terms in Eq. (71–3) correspond to FX, FX/local cross-term, and local returns, respectively. Here, ${}^{b}w_c^P$ and ${}^{b}w_m^P$ represent the "base-currency portfolio market value weights," i.e., the market value of positions in currency c or market m over the market value of the portfolio, both expressed in base currency units. Note that within single-currency markets the cash deposit rate return and the FX return are the same for all securities and therefore the same for the portfolio and the benchmark. However for a generic market m that may span several currencies, the cash deposit rate return $R_m^{depo,P}$ is defined as the weighted average return over all market securities. Since the composition of the market generally differs across portfolios and benchmarks we need to use the designation P to identify a specific portfolio.

FX Hedging

FX hedging—the overlay of FX derivatives with the intent to change the FX exposure profile of a portfolio without affecting its local markets exposures—is a common practice in multicurrency portfolios. It enables managers to disentangle the portfolio construction process between the FX experts and the local market managers. The most common instruments used for hedging are FX forwards, typically with short tenors (e.g., one month) and rolled regularly. Longer tenors are sometimes used to reduce rolling costs.

Despite the intent to leave the local exposures unchanged, in practice FX hedging instruments have side effects that must be accounted for in a complete attribution framework. In what follows we detail two such effects.

Exposure to Local Interest Rates

Ideal FX hedges earn the cash rate in each currency and have zero interest rate duration. In practice, FX hedging instruments do have exposure to the short end of local interest rate curves. This effect is highlighted during market crises, when short rates exhibit significant volatility. Typically, this return is considered part of the hedging return, as it comes from an unintended exposure to local rates through the instruments used to hedge the portfolio and is not part of the local rates strategy decisions.

Cash Balance Effect

As FX rates fluctuate, the mark-to-market of FX forwards becomes nonzero, essentially representing a cash balance (positive or negative). Unless such cash balance is reinvested regularly, it represents an unintended allocation to cash (which is equivalent to leveraging if the balance is negative). This effect can be significant and needs to be highlighted in performance attribution. To that end, one possible solution is to capture this effect explicitly as the difference of the actual portfolio return minus the hypothetical return that would be achieved if the FX hedges cash balance were reinvested daily in the portfolio. Similar to the exposures to local rates, this effect should also be reported as part of the hedging return.

Once these side effects have been accounted for, the effect of FX hedges is restricted to the FX component of the total return and the cross-term; the local component of return remains unchanged.

Outperformance from FX Allocation and Hedging

FX outperformance is defined as the part of total outperformance that is due to fluctuations of the exchange-rates between the base currency and all non-base currencies present in the portfolio or the benchmark. The first two terms of Eq. (71–3), pure FX and the FX/local cross-term, contribute to FX outperformance. We look at them separately in what follows.

Let's denote the effective portfolio exposure to each spot FX rate after hedging with ${}^{b}h_c^P$ and the benchmark one with ${}^{b}h_c^B$. Then, we can represent the *pure FX outperformance* contribution to the portfolio outperformance as follows:

$$ {}^{FX}R^P - {}^{FX}R^B = \sum_c {}^{b}h_c^P \cdot \left(F_c + R_c^{depo}\right) - \sum_c {}^{b}h_c^B \cdot \left(F_c + R_c^{depo}\right) $$

We can now apply the relative allocation model of the top-down decomposition algorithm described in Chapter 69 to get the hedged FX allocation as:

$$ \sum_c \left({}^{b}h_c^P - {}^{b}h_c^B\right) \cdot \left(F_c + R_c^{depo} - R_b^{depo}\right) \tag{71–4} $$

To derive Eq. (71–4), we specifically set the following variables using the notation from Chapter 69: $\alpha_{k,s} = {}^{b}h_c$, $\alpha_k = \sum_c {}^{b}h_c = 1$, $f_{k,c} = F_c + R_c^{depo}$ and

$f_k^H = R_b^{depo}$. The allocation in Eq. (71–4) is typically used to measure pure FX allocation. However, a similar decomposition can be made to the FX outperformance without the hedges. The un-hedged FX allocation would be:

$$\sum_c \left({}^b w_c^P - {}^b w_c^B\right) \cdot \left(F + R_c^{depo} - R_b^{depo}\right) \tag{71-5}$$

Let's now discuss the *FX-local cross-term return*. For simplicity, let's focus only on the portfolio and split it into the original portfolio (P, with weights w) and the portfolio of hedges (H, with weights w–h). As per Eq. (71–3), we know that the portfolio cross-term return is $\sum_c {}^b w_c^P R_c^P F_c^P$. However, the hedge portfolio H pays the deposit rate R_c^{depo} in each currency. Therefore, the net return for the hedged portfolio ($P + H$) is:

$$\sum_c \left({}^b w_c^P R_c^P - \left({}^b w_c^P - {}^b h_c^P\right) \cdot R_c^{depo}\right) \cdot F_c^P$$

We can therefore see that hedges do contribute to the cross-term between FX and local returns. The contribution of the FX-local cross-term return to the outperformance of a portfolio versus a benchmark is calculated as:

$$\sum_c \left({}^b w_c^P R_c^P - {}^b w_c^B R_c^B\right) \cdot F_c^B + \left(\left({}^b w_c^P - {}^b h_c^P\right) - \left({}^b w_c^B - {}^b h_c^B\right)\right) \cdot R_c^{depo} \cdot F_c^B \tag{71-6}$$

Since this term is the product of two returns, its size is usually smaller than either of the two. However over time, the contributions of the cross-term can accumulate (similar to a convexity term) and become significant relative to the local and FX returns. Moreover, the FX cross-term can be a significant component of total return when FX and local returns have opposite signs and similar magnitudes. For example, if FX return is +5% and local return is –4%, the total return is 5% – 4% + 5% × –4% = 0.80%. Without the cross-term the total return would have been 1.00%, so the cross-term of –0.20% reduces total return by 25%. In the extreme, if the two returns are opposite but equal in magnitude, the entire total return is due to the cross-term. While in the majority of the cases the FX/local cross-term is insignificant, it is preferable to account for it explicitly.

In addition to the first two terms of Eq. (71–3) we just explored, the local return and market value effects of the hedging instruments, as well as their trading returns, should be accounted for separately. This allows us to separate any returns from the hedging instruments from the local returns and outperformance that we explore in the next stage of attribution.

Outperformance from Allocation to Local Markets

After the contributions of FX exposure and hedging are taken out, the remaining outperformance is given by:

$${}^L R^P - {}^L R^B = \sum_m {}^b w_m^P \cdot \left(R_m^P - R_m^{depo,P}\right) - \sum_m {}^b w_m^B \cdot \left(R_m^B - R_m^{depo,B}\right) \tag{71-7}$$

There are many different ways to decompose this outperformance into the contributions of the various decision-makers. The most straightforward is to assume that the first decision layer is the allocation of market value exposure to various local markets. After this, each local market is managed separately versus a corresponding benchmark. We can apply the top-down decomposition algorithm from Chapter 69 to define the local market allocation outperformance as:

$$\sum_m \left({}^b w_m^P - {}^b w_m^B\right) \cdot \left(\left(R_m^B - R_m^{depo,B}\right) - \left(R^B - R^{depo,B}\right)\right) \tag{71-8}$$

And the local market management outperformance as:

$$\sum_m {}^b w_m^P \cdot \left(\left(R_m^P - R_m^{depo,P}\right) - \left(R_m^B - R_m^{depo,B}\right)\right) \tag{71-9}$$

Specifically, we use the following notation from Chapter 69 to construct the equations above $\alpha_{k,s} = {}^b w_m$, $\alpha_k = \sum_c {}^b w_m = 1$, $f_{k,s} = R_m - R_m^{depo}$ and $f_k^H = R^B - R^{depo,B}$. Note that this breakdown is equivalent to the *Total Return model* presented in Chapter 70.

If each local market contains securities denominated in the same currency then Eq. (71–9) is simplified to $\sum_c {}^b w_c^P \cdot \left(R_c^P - R_c^B\right)$. The local outperformance within each currency $R_c^P - R_c^B$ can then be decomposed using the general methodology and any of the models described in Chapter 70. If on the other hand local markets span across currencies, then only the *Total Return Model* (see Chapter 70) is directly applicable for the analysis of local market management outperformance. The use of models that require a reference interest-rate curve for the analysis is not straightforward.

Factor-Based Local Markets Allocation

Market value-weighted allocation to markets hides many of the complexities of the decision process of investing across markets. Indeed, allocation of exposure to local markets consists of the aggregation of exposure to each risk factor that drives market returns, such as yield-curve, implied volatility, spreads, and so forth. To better quantify how much risk is taken in a particular local market, we can describe the allocation decision using the appropriate exposure to each risk factor, e.g., interest rate duration for yield-curve, Vega for implied volatility and spread duration for spreads, etc.

Following the methodology described in Chapter 69, we can rewrite Eq. (71–7) by decomposing local returns into the contributions of risk factors as follows:

$$
{}^{L}R^{P} - {}^{L}R^{B} = \sum_{k}\sum_{m_k} {}^{b}w^{P}_{m_k}\alpha^{P}_{k,m_k} f^{P}_{k,m_k} - \sum_{m} {}^{b}w^{P}_{m} R^{depo,P}_{m}
$$

$$
-\left(\sum_{k}\sum_{m_k} {}^{b}w^{B}_{m_k}\alpha^{B}_{k,m_k} f^{B}_{k,m_k} - \sum_{m} {}^{b}w^{B}_{m} R^{depo,B}_{m}\right) \tag{71-10}
$$

As implied by the notation m_k, each factor may use a different set of local markets. We can now separate local outperformance into allocation, management and leverage using different weights for each factor. Specifically, the outperformance due to allocation is:

$$
\sum_{k}\left(\sum_{m_k}\left({}^{b}w^{P}_{m_k}\alpha^{P}_{k,m_k} - {}^{b}w^{B}_{m_k}\alpha^{B}_{k,m_k}\right)\cdot\left(f^{B}_{k,m_k} - f^{H}_{k}\right)\right) - \sum_{m}\left({}^{b}w^{P}_{m} - {}^{b}w^{B}_{m}\right)\cdot R^{depo,B}_{m} \tag{71-11}
$$

While the one due to management is:

$$
\sum_{k}\left(\sum_{m_k} {}^{b}w^{P}_{m_k}\alpha^{P}_{k,m_k}\cdot\left(f^{P}_{k,m_k} - f^{B}_{k,m_k}\right)\right) - \sum_{m} {}^{b}w^{P}_{m}\cdot\left(R^{depo,P}_{m} - R^{depo,B}_{m}\right) \tag{71-12}
$$

Finally, the top-level allocation, or leverage, can be represented as:

$$
\sum_{k}\left(\sum_{m_k} {}^{b}w^{P}_{m_k}\alpha^{P}_{k,m_k} - \sum_{m_k} {}^{b}w^{B}_{m_k}\alpha^{B}_{k,m_k}\right)\cdot f^{H}_{k} \tag{71-13}
$$

Example: Curve Allocation to Local Markets

As an example of the decomposition we just described, consider a portfolio manager that centrally manages the global interest-rate positioning of the portfolio. In this context, we can use the above methodology to separate the local performance of a portfolio into a global curve allocation and excess (of global curve) outperformance. The portfolio manager can use key rate durations to control her exposure to the former and market value weight to control exposure to the latter. We will select the local markets for the decomposition of global interest rates outperformance in a way that each market c corresponds to a unique interest-rate curve. Most of the time this decomposition is equivalent to single currency markets decomposition, yet occasionally this is not the case. For example, it might be preferable to use individual country government curves when analyzing a portfolio of euro-denominated bonds. This methodology allows us to answer successively:

- What was the contribution of the global duration position of the entire portfolio (Global Duration Mismatch)?

- What was the contribution of taking interest rate exposure (sovereign exposure) outside of our reference currency (Local Curve Advantage)?
- What was the contribution of taking other risk exposure in each currency (Excess of Curve Allocation)?

In this example, we will further separate the curve return into two components, a *curve carry* and a *curve change* return. To account for *curve carry* in a way that is consistent with Eq. (71–7), we subtract the deposit return from the outperformance of curve carry. The carry exposure to each individual key-rate point i in each curve c is constructed using the curve-matching portfolio (CMP) weights $\omega_{c,j}$ as described in Chapter 70. The idea behind the CMP is to represent each bond in the portfolio or benchmark as a portfolio of "par bonds" whose curve carry is easy to compute analytically. We can then calculate the carry associated with the portfolio or benchmark using the carry of the corresponding CMP. Let us also denote the curve carry return from each individual key-rate point with $R_{c,j}^{carry} = y_{c,j}\Delta t$. From Eqs. (71–11) to (71–13), using the transformations $\alpha_{k,m_k} = \omega_{c,j}$, $f_{k,m_k} = R_{c,j}^{carry} - R_c^{depo}$ and setting the hurdle rate equal to the excess carry return of a reference currency (typically the base currency of the analysis) $f_k^H = R_{ref,j}^{carry} - R_{ref}^{depo}$, we get the following decomposition.

The local curve carry allocation is given by

$$\sum_c \sum_j \left({}^b w_c^P \omega_{c,j}^P - {}^b w_c^B \omega_{c,j}^B\right) \cdot \left(\left(R_{c,j}^{carry} - R_c^{depo}\right) - \left(R_{ref,j}^{carry} - R_{ref}^{depo}\right)\right) \tag{71-14}$$

The local curve carry management by

$$\sum_c \sum_j {}^b w_c^P \omega_{c,j}^P \cdot \left(\left(R_{c,j}^{carry} - R_c^{depo}\right) - \left(R_{c,j}^{carry} - R_c^{depo}\right)\right) = 0 \tag{71-15}$$

And the global curve carry over deposit as

$$\sum_c \sum_j \left({}^b w_c^P \omega_{c,j}^P - {}^b w_c^B \omega_{c,j}^B\right) \cdot \left(R_{ref,j}^{carry} - R_{ref}^{depo}\right) \tag{71-16}$$

Note that since c represents a single interest rate curve, the carry return at each key-rate point and the deposit rate return is uniform across all securities and therefore the same for the portfolio or the benchmark. In this case the curve carry management is zero by construction. Further, if we do not use a reference curve, then the global curve carry term also becomes zero and the global curve carry outperformance is simply broken down per curve and key-rate point as follows:

$$\sum_c \sum_j \left({}^b w_c^P \omega_{c,j}^P - {}^b w_c^B \omega_{c,j}^B\right) \cdot \left(R_{c,j}^{carry} - R_c^{depo}\right) \tag{71-17}$$

We now turn to the second component of the curve return, the *curve change* return. The outperformance due to curve change is decomposed similarly using

key-rate durations as allocation weights and the negative of the key-rate yield change as return, i.e., $\alpha_{k,m_k} = KRD_{c,j}$, $f_{k,m_k} = -\Delta y_{c,j}$ and $f_k^H = -\Delta y_{ref,j}$.

Under this setting the local yield-curve change allocation is

$$-\sum_c \sum_j \left({}^b w_c^P KRD_{c,j}^P - {}^b w_c^B KRD_{c,j}^B \right) \cdot \left(\Delta y_{c,j} - \Delta y_{ref,j} \right) \tag{71-18}$$

And the local yield-curve change management is

$$-\sum_c \sum_j {}^b w_c^P KRD_{c,j}^P \cdot \left(\Delta y_{c,j} - \Delta y_{c,j} \right) = 0 \tag{71-19}$$

Finally, the global duration mismatch is

$$-\sum_c \sum_j \left({}^b w_c^P KRD_{c,j}^P - {}^b w_c^B KRD_{c,j}^B \right) \cdot \Delta y_{ref,j} \tag{71-20}$$

Once again, within a specific curve interest rate changes are the same for all securities and therefore for the portfolio and the benchmark. This causes the management term to be zero. In addition, if no reference curve is specified, then the global duration mismatch becomes zero as well and the global curve change outperformance is simply broken down per curve and key-rate point as follows:

$$-\sum_c \sum_j \left({}^b w_c^P KRD_{c,j}^P - {}^b w_c^B KRD_{c,j}^B \right) \cdot \Delta y_{c,j} \tag{71–21}$$

Once outperformance from interest rate curve exposures has been accounted for, the remaining return, i.e., the return in excess of FX and curve return can be explained using a different set of local markets using the same methodology discussed above in the "Outperformance from Allocation to Local Markets" section.

Global Curve Allocation in Practice

To illustrate the concepts just developed, let's consider the following example. A U.S. dollar-denominated portfolio is managed against the Barclays Capital Global G4 Treasury Index, an index consisting of government bonds from four currencies, U.S. dollar, euro, Japanese yen and British pound. The manager is allowed to make the portfolio deviate from the index in order to express views that in her opinion will produce superior returns. In this case, the manager believes that euro will strengthen versus the U.S. dollar and at the same time U.S. rates will rise while euro rates will fall. She wants no active exposure to the yen market. Finally, to minimize sovereign risk she prefers to concentrate exposure within the euro-zone to the strongest economies in the region.

The portfolio is constructed in line with the above views as follows:

- The portfolio is long euro (against the U.S. dollar, the base currency of the portfolio).

- The portfolio uses 6-month FX forwards selling Japanese yen against the U.S. dollar to bring the portfolio yen exposure in line with that in the benchmark.
- The portfolio is net long interest-rate duration in euro-denominated securities and net short interest-rate duration in U.S. dollar–denominated securities.
- The portfolio overall interest rate duration is neutral against the benchmark.
- In the euro-zone, only bonds from AAA-rated countries are included in the portfolio.

The major portfolio exposures are summarized in Exhibit 71–1.

Exhibit 71–2 shows the breakdown of the portfolio outperformance versus the benchmark for a period of one month. The total outperformance is +10.5 bp. It is broken down by currency, with U.S. dollar being the top contributor at +15.5 bp. It is also broken down by type of exposures, where we see that FX positioning contributed +14.3 bp, allocation to local markets (including interest rate exposures) contributed +6.5 bp, while local management within each currency market had a negative contribution of –10.3 bp. As expected, most of the FX Allocation outperformance came from the exposure to the euro (+14.4 bp), indicating that the manager's view regarding a strengthening euro was correct. The breakdown also shows a small contribution from hedging effects under Japanese yen, +0.1 bp. As discussed previously, the 6-month JPY/USD FX forwards contributed to non-FX return in two ways: (1) They were exposed to the short end of the yen and U.S. dollar yield-curve movements; and (2) over the attribution period they accumulated nonzero market value and therefore created a cash balance effect.

EXHIBIT 71–1

Portfolio Major Characteristics by Currency

Currency Buckets	Market Value [%]			OAD Contribution		
	Portfolio	Benchmark	Net	Portfolio	Benchmark	Net
Total	100	100	0.0	6.46	6.47	–0.01

EXHIBIT 71–2

Total Outperformance Breakdown by Currency

	Total	U.S. Dollar	Euro	Japanese Yen	British Pound
Outperformance	10.5	15.5	–5.1	0.5	–0.4
FX Allocation & Hedging	14.3	0.0	14.4	0.0	–0.1
Hedged FX Allocation	14.6	0.0	14.8	–0.1	–0.2
FX / Local Cross Term	–0.4	0.0	–0.4	0.0	0.0
Hedging Effects	0.1			0.1	
Local Market Allocation	6.5	16.5	–9.7	–0.3	0.0
Local Yield-Curve	3.1	14.9	–12.0	0.2	0.0
Local Market Allocation Over Curve	3.4	1.6	2.3	–0.5	0.0
Local Management	–10.3	–1.0	–9.8	0.8	–0.3
Asset Allocation	0.6	–1.1	1.3	0.4	0.0
Security Selection	–10.9	0.1	–11.1	0.4	–0.3

Source: Barclays Capital POINT

Both effects are captured in the non-zero hedging effects outperformance. The yield-curve allocation outperformance is +3.1 bp, with U.S. and the euro-zone contributing +14.9 bp and –12.0 bp, respectively. From this perspective and for this period, the views the manager had regarding the movements on the yield-curve played well for him regarding the U.S. dollar, but against him regarding the euro. The local market allocation in excess of the yield-curve totals +3.4 bp. Finally, local management pulled back the overall outperformance. Security selection in the euro-zone, in particular, contributed –11.1 bp to total outperformance.

Let us first look into the FX allocation outperformance in detail (Exhibit 71–3). In line with the fund manager's view, the euro strengthened, producing +306.1 bp of FX plus cash deposit return in excess of the base currency (U.S. dollar) cash deposit return. Since the euro had an average overweight of 4.6% during this period, it contributed +14.8 bp of FX outperformance. This number can be approximated as the product of the average overweight times the excess return of the currency, i.e., $4.6\% \times 306.1 = +14.1$ bp. The number does not tie out exactly with the +14.8 bp outperformance reported in Exhibit 71–3 because in the attribution system it is calculated daily and then compounded taking account of any fluctuations in the exposure. In Exhibit 71–3 one can also observe that FX hedging of the yen exposure cost +8.5 bp of outperformance since the yen also appreciated during this period. However, the reverse could be true should the yen weaken against the U.S. dollar. The return coming from the hedged FX Allocation

EXHIBIT 71–3

FX Allocation Outperformance Breakdown by Currency[3]

Currency Market	FX Rate Begin	FX Rate End	Excess over Base Depo	Average Market Value (%)			Un-hedged FX Allocation	Hedged FX Allocation	FX / Local Cross Term
				Portf	Bmark	Over-weight			
U.S. Dollar	1.0000	1.0000	0.0	24.1	28.6	–4.5	0.0	0.0	0.0
Euro	1.3018	1.3416	306.1	34.4	29.8	4.6	14.8	14.8	–0.4
Japanese Yen	0.0119	0.0123	327.4	34.5	34.5	0.0	8.4	–0.1	0.0
British Pound	1.5574	1.5657	56.3	7.0	7.1	–0.1	–0.1	–0.1	0.0
Total				**100**	**100**		**23.1**	**14.6**	**–0.4**

[3]The hedging effects category is not included here as it has been discussed in the Exhibit 71–2.

Source: Barclays Capital POINT

outperformance for the Japanese yen is close to zero. This shows that the manager was able to implement into the portfolio one of his goals: reduce significantly any volatility related to exposure to the yen.

Next, we look more carefully into the global yield-curve outperformance (see Exhibit 71–4). The portfolio curve carry outperformance is almost flat at –0.1 bp. Most of the outperformance comes from portfolio duration positioning. During the period, yields rose for all G4 curves. However, on a relative basis, euro yields rose less than U.S. dollar yields. Without changing the portfolio overall interest rate duration, the portfolio picked up +3.2 bp of outperformance. This was achieved by going short the interest-rate duration in the U.S. (+16.3 bp) while long duration in the euro-zone (–13.1 bp). Overall, the duration decisions played in favor of the manager. Japanese yen and British pound markets contributed little as their durations have been purposely kept neutral to the benchmark.

The outperformance contributions in Exhibit 71–4 have been calculated using Eqs. (71–17) and (71–21) and taking into account the detailed key-rate exposures of the portfolio in each currency. For the purposes of this example we simplify these equations assuming that the portfolio curve exposure is distributed evenly across all key-rate points. In this case the following simplifications can be made:

$$\sum_c \sum_j \left({}^b w_c^P \omega_{c,j}^P - {}^b w_c^B \omega_{c,j}^B\right) \cdot \left(R_{c,j}^{carry} - R_c^{depo}\right) \approx \sum_c \left({}^b w_c^P - {}^b w_c^B\right) \cdot \left(\overline{R_c^{carry}} - R_c^{depo}\right), \text{ and}$$

$$-\sum_c \sum_j \left({}^b w_c^P KRD_{c,j}^P - {}^b w_c^B KRD_{c,j}^B\right) \cdot \Delta y_{c,j} \approx -\sum_c \left({}^b w_c^P OAD_c^P - {}^b w_c^B OAD_c^B\right) \cdot \overline{\Delta y_c}$$

Here $\overline{R_c^{carry}}$ and $\overline{\Delta y_c}$ represent the average curve carry return and average yield change in each curve.

For example, the average euro yield is about 3.1%, which implies a carry-over deposit return[4] of 23.4 bp over the attribution period (one month). The contribution of the euro market value overweight to curve carry outperformance can be estimated as the market value overweight times the average carry over deposit return, i.e., (34.4% – 29.8%) × 23.4 bp = +1.1 bp. The contribution of the euro duration overweight to curve change outperformance can be estimated as the product of the duration overweight times the negative of the average yield change, i.e., (2.33 – 1.88) × (–28 bp) = –12.6 bp. This is close but not equal to the reported –13.1 bp because of the simplification above as well as the compounding effects over the attribution period. A detailed key-rate level report can be used to gain more insight into the numbers. It is interesting to note that the portfolio market weights in some currencies reported here are different than the ones reported in Exhibit 71–3. In particular, the U.S. dollar weight was 24.1% in Exhibit 71–3 but

4. Euro deposit rate is about 0.3% during the period. Its monthly carry over deposit return can be estimated as (3.1% – 0.3%) / 12.

EXHIBIT 71–4

Global Yield-Curve Allocation Outperformance

Currency Market	Average Yield Level (%)	Carry Over Deposit (bp)	Curve-Matched Market Weight (%)		Average Yield Change (bp)	Duration (years)		Curve Outperformance (bp)		
			Portf	Bmark		Portf	Bmark	Carry	Change	Total
U.S. Dollar	2.7	20.4	21.6	28.6	35.0	1.05	1.50	–1.4	16.3	14.9
Euro	3.1	23.4	34.4	29.8	28.0	2.33	1.88	1.1	–13.1	–12.0
Japanese Yen	1.2	9.1	37.0	34.5	5.0	2.45	2.46	0.2	0.0	0.2

Source: Barclays Capital POINT

is now reported as 21.6%; the yen weight was 34.5% but is now reported as 37.0%; the euro and British pound weights are unchanged. This is because the market value of the JPY/USD forwards has been excluded from the local analysis since such positions are considered FX hedges. The contribution of the cash balance effect is captured in the *hedging effects* category of outperformance as discussed above.

If we analyze the performance by currency as in Exhibit 71–4, we may penalize the fund manager unfairly for the large negative outperformance coming from the Euro exposure. An alternative way to analyze the global curve outperformance is to use a reference curve, as presented in Eqs. (71–14), (71–16), (71–18) and (71–20). This is done in Exhibit 71–5, using the U.S. dollar yield-curve as the reference curve. Although the total curve outperformance remains the same, the breakdown among currencies has changed.

For example, Japanese yen now contributes negatively to the curve carry outperformance. Although the yen has a positive carry over deposit return of +9.1 bp over the month, this return is lower than the U.S. dollar (reference) carry over deposit return of +20.4 bp. Therefore, an overweight in a relatively underperforming currency results in an underperformance. The global carry outperformance can be approximated with the formula

$$\left(\sum_c {}^b w_c^P - \sum_c {}^b w_c^B\right) \cdot \left(\overline{R_{ref}^{carry}} - R_{ref}^{depo}\right)$$

This approximation is always zero since the sum of the weights over all curves of an (unleveraged) portfolio or benchmark is equal to 1. However, since the actual calculation is using exposures at each key-rate point, the exact global carry outperformance may be non-zero.

The euro shows now a *positive* contribution to the curve change outperformance due to better performance relative to the U.S. curve. Its contribution to curve change outperformance is now estimated as – (2.33 – 1.88) × (28 bp – 35 bp) = +3.2 bp, close to the +3.1 bp reported. As concluded before, the manager decision regarding global curve positioning had an overall positive performance for the portfolio during this period. The U.S. curve—being the reference curve—does not contribute to outperformance. The global duration contribution can be estimated using the formula $-(OAD^P - OAD^B) \cdot \overline{\Delta y_{ref}}$, i.e., – (6.46 – 6.47) × 35 bp = +0.3 bp, close to the +0.1 bp reported.

After the yield-curve outperformance has been accounted for, the excess of yield-curve return is split into allocation and management components. Although in general a different set of markets can be used, in this example we will use the same G4 markets used for the curve decomposition. Exhibit 71–6 shows the details of this breakdown. Overall, the allocation of exposure to the four markets has contributed positively (+3.4 bp) with the exposure to the euro market contributing most of it (+2.3 bp). This number can be approximated as the overweight of the euro market times the excess return of the euro market in the benchmark

EXHIBIT 71–5

Global Yield-Curve Outperformance with U.S. as Reference Curve

Currency Market	Avg Yield Level (%)	Carry Over Deposit (bp)	Curve-Matched Market Weight (%)		Average Yield Change (bp)	Duration (years)		Curve Outperformance (bp)

relative to the overall benchmark, i.e., 4.6% × (67.9 bp – 22.5 bp) = +2.1 bp. On the other hand, the local management of excess to curve return in the euro market has not been successful, contributing –9.8 bp to outperformance. The approximate calculation yields 34.4% × (40.5 bp – 67.9 bp) = –9.4 bp. This underperformance can be understood by looking at more detailed issuer-level reports as presented in Chapter 70. In this example, it turns out that the lower-rated EU countries experienced much bigger spread tightening during the period. The concentration in the strongest economies in the region may reduce the portfolio long-term risk, but during this particular period contributed to loss of performance.

DERIVATIVES AND LEVERAGE

Derivative instruments are widely used across asset classes as both hedges and means to express market views. Their payoffs are tied to changes in the values of underlying securities, and their market values do not generally represent the size of the actual exposure to risk factors. In this section, we discuss how a performance attribution model may handle derivative instruments in order to maintain the intuitive and meaningful nature of the results.

Returns and Basis

Returns of derivative instruments can be difficult to measure. The market value of a contract is typically small (or sometimes zero) compared with its notional exposure, and the standard definition of return—profit/loss (P&L) divided by market value—can result in extremely large (or even infinite) values. For example, the market value of instruments that are marked-to-market daily, such as Treasury futures, is guaranteed to be zero at the end of the day, resulting in a theoretically infinite return. To maintain the notion of return as a P&L per unit of investment, we seek to use a denominator that represents the size of the position in terms of its exposure. We refer to this quantity as the "return basis" or simply "basis." One should define an appropriate return basis for each derivative type of interest. Usually, the basis is set equal to the notional amount, although in many cases special rules are used to define the basis in a bond-equivalent way.

To complicate the issue of derivatives further, the standard methodology of multi-period return compounding cannot be applied. Consider the following definition of single- and multi-period returns, where PL_t and R_t are the P&L and return over the period (t–1, t). The portfolio return is given by

$$R_t = \frac{PL_t}{MV_{t-1}}$$

And the multi-period return is:

$$R = \left(\prod_{t=1}^{T} (1 + R_t) \right) - 1$$

By using market value as a basis for the return and compounding it with the above formula, we get an intuitive relationship between the market values at t = 0 and t = T, and the return over the period (0, T).[5]

$$MV_T = MV_0\,(1+R)$$

Changing the basis to a quantity that is not proportional to the market value will annul this property. This is more evident when returns are large. As an exaggerated example, consider a futures contract that is marked to market daily and therefore always has zero market value. A reasonable basis for returns for a position in this contract is the notional amount invested. Suppose the notional amount is $1,000 and that over two days, the contract produces a mark-to-market P&L of –$500 and $1,000, respectively. Using the notional amount as the basis of returns, the returns for the two days are –50% and +100%, respectively. Using the chain rule to compound returns yields zero return over the two days: $(1-50\%)\times(1+100\%)-1=0\%$. Obviously, this is not consistent with the positive P&L of $500 produced over the two days. Such effects are always present when compounding returns using a basis that is different from the market value of the position; however, their effect is much smaller when the magnitude of returns is small. To avoid such nonintuitive results, one should make appropriate adjustments to the compounding of returns of derivative securities—something out of the scope of this chapter.

Returns for Portfolios and Sectors Containing Derivatives

The return of each individual derivative contract is defined using its basis as described above. However, in typical portfolios, these contracts coexist with cash securities. When we analyze partitions of the portfolio, such as sector or rating, that contain both cash and derivative securities, it is still typical to use market value as the denominator for all returns and weights.[6] Nevertheless, the presence of the derivatives imposes some changes into the analysis.

Let's define the leverage ratio for each security, β_i, to be the basis divided by the market value of the security. Then the leveraged weight of the security is the product of the market value weight and the leverage ratio, $w_i\beta_i$. The return of the portfolio or sector can then be written as the leveraged weighted sum of the deleveraged return of each security:

$$R^P = \sum_i \frac{PL_i^P}{MV^P} = \sum_i \frac{MV_i^P}{MV^P}\frac{basis_i^P}{MV_i^P}\frac{PL_i^P}{basis_i^P} = \sum_i w_i^P \beta_i^P R_i^P$$

5. We assume that the portfolio has no significant cash flows. When such cash flows do occur, the above formula does not hold. For more details, refer to time-weighted versus money-weighted return discussion in Chapter 71.

6. Net (or gross) basis and gross market value could also be used as the denominator for the entire portfolio when analyzing highly leveraged or long-short strategy funds.

Although this transformation does not change the return, notice that the leveraged weights are no longer constrained to sum to 1 when derivatives are present in the portfolio.

$$\sum_i w_i \beta_i \neq 1$$

Therefore, when we seek to explain the contribution of each instrument to the security selection outperformance of each bucket (the last step of the top-down decomposition—see Chapter 69), derivatives give rise to an additional term of outperformance that comes from the implicit leverage they introduce. The example below illustrates this issue.

Example: Leverage from Derivatives and Security Selection Outperformance

Consider a bucket with a single credit security A experiencing excess of curve return of +10%, while the corresponding benchmark bucket has two equally weighted securities, the one in the portfolio A and another one B returning 0%. The total return for that bucket in the benchmark is therefore +5%. Let us also assume that the market value weight of this bucket in the portfolio is 20%; therefore, its contribution to security selection would typically be calculated as 20% × (10% – 5%) = 1.0%. The contribution of security A to security selection is calculated as 20% × (100% – 50%) × (10% – 5%) = 0.5%, and the one of security B is 20% × (0% – 50%) × (0% – 5%) = 0.5%.

Now assume that the portfolio also contained a short protection credit default swap on the issuer of bond A with a return basis equal to the market value of A, essentially doubling the exposure to the issuer of A. Let us assume that the default swap is at-the-money, i.e., its market value is zero, and that it also experiences a return of +10% (using notional as the return basis). Since the market value of the portfolio bucket remains the same but its P&L doubles, the return of the sector is now reported as +20%, and the security selection term becomes 20% × (20% – 5%) = 3.0%. Notice that the market value weight of the bond remains 100% and that the default swap also has a weight of 100% (return basis over market value of the bucket). Bonds A and B contribute to security selection 0.5% exactly as before. The default swap contributes 20% × (100% – 0%) × (10% – 5%) = 1.0%. The contributions of the three securities to security selection sum to 2.0%, leaving 1.0% of security selection unexplained.

This comes from the leverage introduced to the bucket. Indeed, the sum of securities weights in the portfolio is 200%, whereas in the benchmark it is 100%. This causes an outperformance of 20% × (200% – 100%) × 5% = 1.0%, completing the decomposition of security selection. This term was introduced as the "top-level exposure" for the excess return model in Chapter 70 (see Eq. (70–6)).

Typically, in the presence of derivatives, this top-level term can be reported as a separate line item for each bucket–bucket leverage, and folded into the security selection term. Alternatively, it can be reported as leverage at the portfolio level.

A General Framework for Leverage

Leverage complicates portfolio returns calculations and comparison to the benchmark. Furthermore, there are different means to achieve leverage, and the decision to employ it can occur at any level of the portfolio management decision structure. For instance, cash borrowing can be used to leverage the entire portfolio, while derivatives can be used to leverage specific sectors. The latter case can be further distinguished into a decision made by an asset allocator or by a sector manager. Below, we outline an analytical way to account for leverage in a consistent framework with the one discussed in Chapter 69.

We expand the concept of leverage ratio as introduced before and apply it to the entire portfolio. We assume that a "funded" market value—generally different from the actual market value—can be defined for the portfolio, partition buckets and individual securities, and serve as the *basis* for the calculation of unleveraged returns. The ratio of the returns basis to actual market value is the leverage ratio of the portfolio.

$$R^P_{leveraged} = \frac{basis^P}{MV^P} \cdot \frac{PL^P}{basis^P} = \beta^P R^P$$

We can also recursively break down the portfolio return into the contributions of its various sectors by appropriately defining the leverage ratio of each sector:

$$R^P_{leveraged} = \sum_s \frac{PL^P_s}{MV^P} = \sum_s \frac{MV^P_s}{MV^P} \cdot \frac{basis^P_s}{MV^P_s} \cdot \frac{PL^P_s}{basis^P_s} = \sum_s w^P_s \beta^P_s R^P_s$$

Using similar terminology for the benchmark, the total leveraged outperformance can be expressed as a function of leverage ratios and unleveraged returns as:

$$R^P_{leveraged} - R^B_{leveraged} = \beta^P R^P - \beta^B R^B = \sum_s w^P_s \beta^P_s R^P_s - \sum_s w^B_s \beta^B_s R^B_s$$

We will now consider the different ways to break down the total outperformance into contributions from asset allocators and sector managers. It is worthwhile to note that when leverage is allowed, there is no limit to how much exposure managers can allocate to sectors or securities. Consequently, it no longer makes sense to compare sector returns against a hurdle rate (as discussed in Chapter 69) to determine the contribution from asset allocation decisions.

Separate Allocation of Market Weight and Leverage of Each Sector

In this case, each sector is given a market value budget, but sector managers are free to take leverage within their sectors. Separate agents determine the market value allocation and the leverage in each sector. The simple asset allocation/sector

management equations can be readily applied in this case. The comparison of sector returns of the portfolio and the benchmark occurs on a leveraged basis. In this case, the outperformance from leverage decisions is embedded in the sector management term. Specifically, the asset allocation would come as

$$\sum_s \left(w_s^P - w_s^B\right) \cdot \beta_s^B R_s^B \tag{71-22}$$

And the sector management as

$$\sum_s w_s^P \cdot \left(\beta_s^P R_s^P - \beta_s^B R_s^B\right) \tag{71-23}$$

Allocation of Total Exposure to Sectors

Alternatively, leverage can be determined by the asset allocator instead of the sector managers. In this case, a single agent decides the total exposure[7] to the unleveraged return of each sector. Once again, the asset allocation/sector management equations can be applied, but we now need to use total exposure instead of market value as the allocation weight. In this case, the outperformance from leverage decisions is embedded in the asset allocation term. The asset allocation is

$$\sum_s \left(w_s^P \beta_s^P - w_s^B \beta_s^B\right) \cdot R_s^B \tag{71-24}$$

While the sector management comes as

$$\sum_s w_s^P \beta_s^P \cdot \left(R_s^P - R_s^B\right) \tag{71-25}$$

In general, we can assume that leverage decisions are made at both the portfolio and the sector levels. A top-level manager may determine the total portfolio leverage (relative to the benchmark), and an asset allocator may subsequently determine the total exposure to each sector. Therefore, if total leverage is determined at the portfolio level, then the allocation of total exposure to each sector is constrained by the portfolio leverage decision and must be measured relative to that. Instead of using the absolute total exposure as the allocation weight, we now need to use the relative total exposure (total exposure divided by the portfolio/benchmark leverage). We also need to use a hurdle return, as exposure at the sector level is partially constrained.

In this scenario the outperformance decomposition has some extra terms, as shown below. The asset allocation outperformance can be derived as

$$\beta^P \sum_s \left(\frac{w_s^P \beta_s^P}{\beta^P} - \frac{w_s^B \beta_s^B}{\beta^B}\right) \cdot \left(R_s^B - R^H\right) \tag{71-26}$$

7. The total exposure is defined here as market weight times leverage.

While the sector management comes as

$$\sum_s w_s^P \beta_s^P \cdot \left(R_s^P - R_s^B\right) \tag{71-27}$$

The top-level leverage is

$$\left(\beta^P - \beta^B\right) \cdot R^H \tag{71-28}$$

If we do not assume that leverage aggregates linearly, i.e., generally $\beta^P \neq \sum_s w_s^P \beta_s^P$ and $\beta^B \neq \sum_s w_s^B \beta_s^B$ in order to keep the decomposition complete we need to add an additional term, that we call "diversification."

$$\left(\sum_s w_s^P \beta_s^P - \beta^P \frac{\sum_s w_s^B \beta_s^B}{\beta^B}\right) \cdot R^H \tag{71-29}$$

If we assume no leverage in the benchmark, the diversification term becomes

$$\left(\sum_s w_s^P \beta_s^P - \beta^P\right) \cdot R^H$$

Moreover, this term is zero if the leverage is aggregated linearly; that is,

$$\beta^P = \sum_s w_s^P \beta_s^P, \quad \beta^B = \sum_s w_s^B \beta_s^B$$

However, there are situations where we may not want the leverage to aggregate linearly. As an example, suppose that betas are defined based on risk. Then, if the different sectors are not perfectly correlated, the beta of the portfolio would tend to be smaller than the sum of the individual sector betas. This is due to the well-known risk diversification effect, hence the name for this term. In this case, the leverage creates a diversification effect with positive returns for our portfolio as long as the hurdle rate return is positive.

Handling leverage is a generalization of the top-down decomposition algorithm described in Chapter 69, where unleveraged returns are the factor returns, leveraged weights are the factor loadings and we assume linear aggregation of leverage (so that the diversification term vanishes). This analysis is also similar to the one regarding the decomposition of the spread related outperformance, described in Chapter 70.

Special Handling of Certain Derivative Types

Often, derivatives are used to manage a specific type of risk exposure and are not meant to participate in the general asset allocation/security selection

portfolio management framework. We already encountered this issue earlier in this chapter, while discussing how to handle the role of currency derivatives as FX hedging instruments. A similar situation arises with interest-rate derivatives as instruments of managing interest-rate risk only. In both cases we have to account for the return that is not tied to their primary hedging function and for the implicit cash allocation that occurs when derivative instruments used as hedges acquire market value between rebalancing dates. On the other hand, credit derivatives are typically used along with cash instruments to manage exposures to sectors and issuers; therefore they do participate in asset allocation and security selection. Depending on the portfolio and level of analysis, we may want all these different effects to be captured and reported separately. Below, we discuss in more detail issues arising from the handling of common derivatives and the treatment typically adopted.

Currency Derivatives

FX forwards are typically used as FX hedging instruments. In this case, their return and outperformance contributions should not be allowed to affect the local (excess of FX) outperformance analysis. As discussed previously in this chapter the easiest way to achieve this is to remove them completely from the analysis of non-FX outperformance. However, removing FX hedges from the local analysis introduces two side-effects that have to be explicitly accounted for: (a) The non-FX return of FX hedges must be recorded. Such return can be non-negligible in periods of market crisis or whenever hedges with longer tenors are being used. (b) Since FX hedges are not being rolled daily, they accumulate market value which represents an allocation to cash, if positive, or leverage, if negative. This effect—called earlier as the "FX hedging cash balance effect"—contributes to outperformance and should be appropriately recorded.

Interest Rate Derivatives

Derivatives designed to hedge or gain exposure to interest rate factors are typically overlays onto a portfolio after the core positions are chosen. These instruments, such as government bond futures and interest rate swaps, typically affect the curve return of the portfolio but have little effect on the excess return over yield-curve. Typically, they are used in portfolios that lend themselves to attribution models that treat curve outperformance separately (e.g., the excess return model discussed in Chapter 70). In these models, interest rate derivatives should only contribute to the curve outperformance, which is a common factor, and they should be removed entirely from the decomposition of the allocated factors. Two portfolios identical except for the use of interest rate derivatives should have the same asset allocation and security selection returns.

Similar to currency hedges, the removal of interest rate derivatives from the asset allocation/security selection outperformance analysis introduces a cash-balance effect if the market value of such derivatives is non-zero. Indeed, a positive market value indicates an implicit allocation to cash, whereas a negative

market value indicates implicit borrowing and, therefore, leverage. Further, exchange-traded derivative instruments may incur return that cannot be explained by their curve exposures. For example, Treasury futures frequently trade at a spread to their theoretical fair value. Changes in this spread result in return that cannot be explained by interest rate movements. However, this return should be accounted for and reported as a side-effect of interest rate hedging.

Credit Derivatives

In contrast to currency and interest rate derivatives, credit default swaps (CDS), credit index default swaps (CDX or iTraxx), and total return swaps (TRS) are primarily used to manipulate exposure to excess (over curve) return factors. Typically, these instruments are included in the regular asset allocation/security selection decomposition. Single issuer credit default swap instruments have small interest-rate exposure which does contribute to the yield-curve outperformance, but their primary exposure is to the credit factor of the underlying issuer. The performance of credit default swap indices should be explained by exploding them into their single-issuer constituents. The constituents are then included in the asset allocation/security selection decomposition, ensuring that the correct weights and returns are used to reflect the actual exposure to each partition bucket. The basis of returns for credit derivatives is not their market value. As a result, they generate bucket leverage, as discussed previously.

FROM THEORY TO PRACTICE

In order to be of any practical use, a performance attribution system must deal with a significant number of special situations that arise in day-to-day portfolio management. Such issues include missing security prices or analytics, bad prices or analytics, intra-period transactions, settlement conventions, pricing discrepancies between the portfolio and its benchmark, and so on. Below, we discuss some of these issues.

Return and Outperformance Compounding[8]

Multi-period arithmetic total return is compounded by taking the product of the single-period total returns:

$$R = \left(\prod_{t=1}^{T} (1 + R_t) \right) - 1$$

As discussed in Chapter 69, a general framework of performance attribution begins with the splitting of a single-period total return into the contributions

8. For an introduction to multi-period attribution and compounding see Chapter 69.

of various factors, $R_t = \sum_k \alpha_{k,t} f_{k,t}$. This leads to the question of how the return splits should be compounded so that the sum of the compounded return splits remains equal to the compounded total return. This is necessary to satisfy the additivity and completeness requirements of attribution.

One way to accomplish this is the following: Let us designate with $\hat{R}_k$ the multi-period compounded factor return. Setting $\hat{R}_k$ equal to the single-period factor return, $f_{k,t}$, scaled by the compounded portfolio value at the beginning of the period, i.e.,

$$\hat{R}_k = \sum_{t=1}^{T} \alpha_{k,t} f_{k,t} \prod_{s=1}^{t-1} (1 + R_s), \qquad \text{where} \qquad \prod_{s=1}^{0} (1 + R_s) \equiv 1 \tag{71-30}$$

guarantees the additive decomposition of total multi-period return, i.e., $R = \sum_k \hat{R}_k$. This decomposition algorithm is fairly straightforward and has the properties of additivity and completeness, but what about fairness?

Consider a simple example with two factors and two periods. Let us assume that both factors contribute 20% return, but factor A does so in the first period and has zero return in the second period, while factor B has zero return in the first period and 20% return in the second period. The total portfolio return is therefore (1 + 20%) × (1 + 20%) – 1 = 44%. According to the algorithm above, the contribution of the first factor is not scaled because it occurs in the first period and remains at 20%; the contribution of the second factor is scaled by the portfolio value at the end of the first period (1.20) so it becomes 24%. Although one could argue that the decomposition is unfair—as it favors the second factor which contributed returns after the first factor—the notion that later returns and contributions can be affected by the earlier performance of the portfolio as a whole is generally accepted as a fair practice.

In addition to the total return and return splits compounding, any multi-period attribution algorithm also needs to address the compounding of outperformance. In the context of simple factor-based performance attribution models the above algorithm can be readily applied:

$$R^P - R^B = \sum_k \left(\hat{R}_k^P - \hat{R}_k^B \right)$$

However, in the context of a general attribution model where the categories to which outperformance is decomposed to may depend both on the portfolio and the benchmark (e.g., asset allocation or security selection), such simple decomposition is not possible and more complex algorithms must be used.

Since single-period performance attribution provides a complete, additive and fair decomposition of single-period outperformance, most compounding algorithms seek to define scaling coefficients for each period, such that the sum

of the scaled single-period outperformance is equal to the total multi-period outperformance.[9]

$$R^P - R^B = \sum_t \beta_t \left(R_t^P - R_t^B\right)$$

Once β_t is determined, it can be used to scale every outperformance component (e.g., yield-curve, asset allocation, security selection, etc.) because of the additivity and completeness properties of single-period performance attribution.

One commonly used approach in practice is the optimized linking coefficient approach.[10] The basic idea behind this approach is to seek coefficients which avoid extreme values under most scenarios. Indeed, if not carefully defined, such coefficients can become zero or attain very high values distorting the outperformance decomposition and making it unfair. The value of β_t in the optimized-linked method is determined as follows:

$$A = \frac{\left(R^P - R^B\right)/T}{\left(1+R^P\right)^{1/T} - \left(1+R^B\right)^{1/T}}$$

$$C = \frac{R^P - R^B - A\sum_{t=1}^{T}\left(R_t^P - R_t^B\right)}{\sum_{t=1}^{T}\left(R_t^P - R_t^B\right)^2}$$

$$\beta_t = A + C\left(R_t^P - R_t^B\right)$$

Transactions

Return and outperformance calculations require special treatment of transactions. Security transactions which usually settle on a forward basis create "intra-period" returns as well as "unsettled" positions. It is important to recognize intra-period return separately because it does not participate in the decompositions previously discussed. It is also important to make the distinction between settled and unsettled positions because only the settled positions earn carry.

Intra-Day Return

Daily attribution models compound returns and outperformance using end-of-day market-closing prices. However, the models should allow users to enter transactions that occur during the day at the actual transaction prices, which can be quite

9. The exact nature of the algorithm that should be used to link the results of a multi-period attribution has been the subject of intense debate in the performance attribution literature. The entire Fall 2002 issue of the *Journal of Performance Measurement* was devoted to this topic.
10. Jose Menchero, "An Optimized Approach to Linking Attribution Effects over Time," *Journal of Performance Measurement* (Fall 2000), pp. 36–42.

different from the closing prices of the traded security used to calculate daily returns. This flexibility guarantees that the returns of the portfolio, including trading activities, are captured accurately. The difference between the trade price and the closing price should be captured and reported separately as "Trading" return. Further, the return contribution from intra-day trading activities, which is not captured by the end-of-day portfolio snapshots, must also be accounted for and reported as "Intra-Day Trading" outperformance.

Unsettled Positions

Most security transactions settle on a forward basis; i.e., both cash and the security are exchanged some days in the future. For example, corporate securities transactions settle after three business days (T+3), while most government securities settle after one day (T+1). Certain mortgage-backed securities (TBAs) have special settlement rules as they settle on a specific day each month. A comprehensive attribution model should allow transactions to settle on any forward date.

While buyers of a security are exposed to its clean price fluctuations (market risk) immediately after the transaction, they do not begin earning the coupon return of the security (more accurately, the yield or time return of the security r^{carry}) until after the settlement date. Instead, they keep earning the yield on the cash (r^{cash}) that they have promised to pay on the settlement date. Therefore, an unsettled position in a portfolio is earning a return equal to $r^{cash} + r^{price}$, while the same security in an index, always settled, is earning $r^{yield} + r^{price}$. The return $(r^{cash} - r^{yield}) \cdot \Delta t$, where Δt is the time to settlement, constitutes real outperformance (usually negative) that must be accounted for. Conversely, when the portfolio sells the position, it is earning the security yield (instead of cash) until the sell settlement date, making back any yield lost when the security was bought. These effects should be captured by the outperformance algorithm and reported for each model as carry outperformance.

Handling Inconsistent or Missing Data

Security prices used to compute returns of benchmark indices may be different from what portfolio managers use to mark their positions.[11] For any outperformance decomposition to be meaningful, it is important for the price and, hence, the return of the same security to be consistent in both universes. In most cases, managers would want to use their own prices to compute their portfolio returns. In general, we should use the security returns from the portfolio by default. However, since the total return of the benchmark index typically needs to be consistent with the published number, the algorithm should allow for the pricing difference effect to be reported as a separate source of outperformance.

11. This is not uncommon for less liquid securities.

When there are missing prices during the attribution period, the system can either exclude the securities from the analysis entirely or imply prices if that is deemed reasonable. During the period with missing prices, one can use last available analytics and market changes to imply prices so that daily outperformance can be computed. This approach is particularly useful if prices for the beginning and end of the period are available so that the correct return over the attribution period is known.

KEY POINTS

- Multi-currency portfolios add an additional layer of complexity to the portfolio management structure. An attribution algorithm normally needs to decompose the global total outperformance into FX and local market allocations, as well as local management.
- Being able to accurately separate the performance due to active foreign-exchange (FX) positions from that due to the hedging effects is a complex but particularly important task in any multi-currency attribution system.
- Factor-based local market allocation, such as duration-based global curve allocation, quantifies better the risk and return in a particular market than the market-value weighted local markets allocation.
- Derivatives change the nature of the basis used to define returns. They often require special treatment in order to obtain intuitive and meaningful attribution results.
- Return and outperformance compounding is an important task in order to ensure the additivity and completeness properties for any multi-period attribution.
- A complete attribution system should be able to handle intra-day transactions, unsettled positions as well as missing and inconsistent prices.

METHODOLOGY FOR CALCULATING CURRENCY EXPOSURES IN BOND PORTFOLIOS AND INDEXES

CURT HOLLINGSWORTH
Portfolio Manager
Fidelity Investments

In an unhedged global bond portfolio, currency exposures are responsible for most of the return volatility. As a result, it is worth taking the time to calculate currency exposures accurately. This Appendix provides a methodology for calculating the currency exposures in a bond portfolio as of the close of the most recent portfolio pricing date. This methodology can also be used to calculate the currency exposures in Citigroup indexes and Barclays Capital indices.

It is assumed that each currency exposure will be calculated as part of an automated overnight batch process. When calculating currency exposures, there are a number of approaches that can be used. As a result, it may be helpful to define a few guiding principles at the outset:

1. If a portfolio is structured so that it exactly replicates its index, then the portfolio and the index should have the same currency exposures. In other words, each currency exposure that one calculates for the portfolio should exactly match the corresponding currency exposure that one calculates for the index.
2. If a security is held by both the portfolio and the index, then one should use the same price for the portfolio and the index.
3. For each actual price in the bond market, there is an associated settlement date. The price and the settlement date go together; they are joined at the hip. When calculating accrued interest or analytics, one should use the settlement date that goes with the price.
4. For the portfolio, identify the most reliable source for the net assets as of the close of the most recent portfolio pricing date. Use these net assets when calculating currency exposures.

5. Intra-month, for the index, use the cash positions from the index provider. Do not calculate these cash positions for the index. (Doing so is difficult for government/credit indices, and almost impossible for aggregate bond indices.)

These five guiding principles seem reasonable enough. However, except for very simple portfolios and indexes, it is impossible to adhere to all five of them at once. As a result, when calculating currency exposures, one needs to make a few tradeoffs and arbitrary decisions, and there will likely be a few inconsistencies in the end result. The methodology described in this Appendix was designed to adhere as closely as possible to these five guiding principles, minimize operational risk, and produce extremely accurate results.

A brief word on scope: In order to provide a fully defined methodology in a reasonable number of pages, it is assumed that the portfolios:

1. Invest only in the types of securities that are constituents of investment-grade global bond indexes, such as the Citigroup World Government Bond Index (WGBI) and the Barclays Capital Global Aggregate Bond Index.
2. Execute standard FX trades.
3. Maintain cash balances in foreign currencies.

Thus, derivatives, TBAs, and many other instruments are out of scope. In addition, FX forward outrights with more than one year from the most recent portfolio pricing date to the value date are out of scope. Finally, no adjustments for "bad days" are made in the discussion below. A bad day occurs when a security is scheduled to make a principal or interest payment on a weekend or holiday.

MAIN FORMULA FOR BOND PORTFOLIOS

The following formula can be used to calculate a bond portfolio's exposure to a single currency:

Currency Exposure (A) =

Market Value of Securities (B)
+ Cash Balance (C)
+ Unsettled Sells of Securities (D)
– Unsettled Buys of Securities (E)
+ Unsettled Buys of Currency (F)
– Unsettled Sells of Currency (G)
+ Coupon Payments for Gilt Holdings (H)
+ Coupon Payments for Unsettled Sells of Gilts (I)
– Coupon Payments for Unsettled Buys of Gilts (J)

+ Coupon Payments for Unsettled Sells of Non-Gilts (K)
– Coupon Payments for Unsettled Buys of Non-Gilts (L)
+ Interest Payments for Agency MBS Holdings (M)
+ Principal Payments for Agency MBS Holdings (N)
+ Interest Payments for Unsettled Sells of Agency MBS (O)
+ Principal Payments for Unsettled Sells of Agency MBS (P)
– Interest Payments for Unsettled Buys of Agency MBS (Q)
– Principal Payments for Unsettled Buys of Agency MBS (R)

Currency Exposure (A) is the portfolio's exposure to a single currency as of the close of the most recent portfolio pricing date. This currency exposure is expressed in the local currency. It has not been converted to the base currency of the portfolio. This main formula for bond portfolios can also be used to calculate a portfolio's exposure to the base currency of the portfolio.

There are 17 inputs that are needed in order to calculate this currency exposure. All of the 17 inputs should be expressed in the local currency. In other words, they should not be converted into the base currency of the portfolio.

For the Unsettled Buys of Currency (F) and the Unsettled Sells of Currency (G), one needs to calculate their present values before using them as inputs to the main formula for bond portfolios.

The inputs are defined below and other definitions are provided in Exhibit A–1.

EXHIBIT A–1

Defined Terms for Bond Portfolios

Accrued Interest: For non-factoring securities:

Accrued Interest = Par Amount × (Accrued Interest Factor/100)

For factoring securities:

Accrued Interest = Current Face × (Accrued Interest Factor/100)

Accrued Interest Factor: The accrued interest factor is used to calculate the accrued interest and the market value for each of the securities held by the portfolio.

- For a U.S. Treasury bond, the accrued interest factor for a specific settlement date is the accrued interest for a hypothetical trade that was executed with a par amount of USD 100.00.
- For a gilt, the accrued interest factor for a specific settlement date is the accrued interest for a hypothetical trade that was executed with a par amount of GBP 100.00.

For each of the securities held by the portfolio, use the following hierarchy in order to determine the accrued interest factor:

- In-house quantitative models
- Bloomberg

(*Continued*)

EXHIBIT A–1

Defined Terms for Bond Portfolios (*Continued*)

Adjusted Net Assets: Two minor adjustments to net assets should be made:

$$\text{Adjusted Net Assets} = \text{Net Assets} + \text{Shareholder Activity} + \text{Dividend Payable}$$

Analytics: Metrics such as yield to worst, modified duration, option adjusted spread, option adjusted duration, option adjusted convexity, and key rate durations are all examples of analytics.

Base Currency of the Portfolio: For a mutual fund, this is the currency in which the net asset value is denominated.

Bond Trades: Bond trades are trades involving the types of instruments that are included in the securities held by the portfolio when calculating Market Value of Securities (B) for a portfolio. (See the definition of "Securities Held by the Portfolio.")

Books and Records: The official record of the portfolio's holdings and net assets. For most mutual funds, the same entity that is responsible for maintaining the books and records is also responsible for calculating the fund's net asset value on each day that the fund is open.

Compounding Frequency: All analytics (including yield to worst) should be calculated assuming semiannual compounding.

Cross-Currency FX Trades: An FX trade where the base currency of the portfolio is not one of the currencies in the currency pair.

Currency Exposure: This is a portfolio's exposure to a single currency. The currency exposure, by definition, is always calculated and expressed in the local currency. (Later on in the overnight batch process, the currency exposure can be converted to the base currency of the portfolio and called something else.)

Dividend Payable: For those mutual funds that declare daily dividends and pay them monthly, this is the month-to-date sum of these daily dividends.

Exchange Rates—Closing Spot Rates: The following hierarchy should be used in order to determine the closing spot rates for the portfolio:

- Books and records
- Index provider (for the index that is used as the benchmark for *this* portfolio)
- WM/Reuters
- Bloomberg

Exchange Rates—Closing Forward Rates: The following hierarchy should be used in order to determine the closing forward rates for the portfolio:

- Books and records
- Index provider (for the index that is used as the benchmark for *this* portfolio)
- WM/Reuters
- Bloomberg

Ex-Coupon Date: Gilts go *ex*-coupon (or ex-dividend) seven business days before each coupon payment date. This means that if the settlement date of a trade involving a gilt falls after the seventh business day before a coupon payment date, the seller will receive the entire coupon payment. As a result,

EXHIBIT A–1

Defined Terms for Bond Portfolios (*Continued*)

if the settlement date of a trade involving a gilt falls after the seventh business day before a coupon payment date and falls before this coupon payment date, then the trade will settle with a negative accrued interest. This negative accrued interest will be subtracted from the bond's clean price. (The one exception is the 3.5% War Loan, which is a perpetual and goes *ex*-coupon 10 business days before its coupon payment dates on June 1 and December 1. This gilt is not in the WGBI.)

Factoring Securities: These securities include:

- Asset-backed securities (ABS)
- U.S. agency mortgage-backed passthrough securities
- Commercial mortgage-backed securities (CMBS)
- Enhanced equipment trust certificates (EETC)

Foreign Currencies: Any currency that is not the base currency of the portfolio.

Index Pricing Date: The date on which the index was priced by the index provider. The index pricing date should be the same as the most recent portfolio pricing date.

Local Currency: The currency in which a security or a cash balance is denominated.

Market Value: Throughout this Appendix, this value is always assumed to include accrued interest. In order to calculate the market value for each of the securities held by the portfolio, use the following formulas:

$$\text{Market Value} = \text{Principal} + \text{Accrued Interest}$$

$$\text{Principal} = \text{Par Amount} \times (\text{Price}/100)$$

$$\text{Accrued Interest} = \text{Par Amount} \times (\text{Accrued Interest Factor}/100)$$

Most Recent Portfolio Pricing Date: For a mutual fund, this is the most recent day on which a net asset value was calculated.

Net Assets: The market value of the portfolio as of the close on the most recent portfolio pricing date. In other words, if the entire portfolio were liquidated, this is the amount of money that would be returned to the shareholders and clients. For a mutual fund,

$$\text{Net Assets} = \text{Number of Shares Outstanding} \times \text{Net Asset Value per Share}$$

Non-Factoring Securities: These securities include the following types of bonds:

- Treasury
- Government-related
- Corporate

Par Amount: For non-factoring securities, use the par amount from the books and records for the portfolio. For factoring securities, use the current face from the books and records for the portfolio.

Present Value: Calculated for each unsettled FX trade where there are more than four business days between the most recent portfolio pricing date and the value date for the unsettled FX trade. For each unsettled FX trade, take both

(*Continued*)

EXHIBIT A–1

Defined Terms for Bond Portfolios (*Continued*)

currencies in the currency pair into account and calculate the present value of the currency amount for each one separately. In order to calculate the present value of the currency amount, use the following formula:

$$PV = C/(1 + R/100 \times N/B)$$

PV = Present value of the currency amount

C = Currency amount on the value date

R = Interest rate expressed as a percentage per annum

N = Actual number of days from the most recent portfolio pricing date to the value date

B = Day count basis (usually either 360 or 365, depending on the currency)

- Using four business days as the cutoff is admittedly arbitrary. For most trades involving securities, regular settlement is T + 4 business days or shorter. As a result, using four business days as the cutoff will allow one to avoid calculating present values for unsettled FX trades that were executed to fund the settlement of these securities trades. This in turn will simplify things and reduce operational risk, while having a *de minimus* impact on the calculated currency exposures.
- For most currencies, for the interest rate, one should use the Eurodeposit rate for funds deposited in that currency. These Eurodeposit rates are provided by Citigroup. In addition, these Eurodeposit rates can be obtained from market data services such as Bloomberg and Reuters. See *Citigroup Global Fixed-Income Index Catalog, 2011 Edition* (February 8, 2011); the Reuters Instrument Codes (RICs) used to obtain monthly yields (bid) for Eurodeposits are provided for 18 currencies on page 61.

Price: Price is expressed as a percentage of the par amount (or current face). For each of the securities held by the portfolio, use the following hierarchy in order to determine the price:

- Books and records
- Index provider (for the index that is used as the benchmark for *this* portfolio)
- Bloomberg

For each of the securities held by the portfolio, the same price that is used to calculate the principal and the market value should also be used to calculate *all* of the analytics.

Principal: For non-factoring securities:

$$\text{Principal} = \text{Par Amount} \times (\text{Price}/100)$$

For factoring securities:

$$\text{Principal} = \text{Current Face} \times (\text{Price}/100)$$

Securities Held by the Portfolio: These are all of the portfolio positions that should be included when calculating the Market Value of Securities (B) for all of the currency exposures in the portfolio. These portfolio positions should be based on the trade date holdings (not the "settlement date holdings") as of the close on the most recent portfolio pricing date. These portfolio positions should include:

- Factoring securities
- Non-factoring securities

EXHIBIT A–1

Defined Terms for Bond Portfolios (*Continued*)

These portfolio positions should exclude the following:

- Items "C" through "R" in the main formula for bond portfolios

Settlement Date: For each of the securities held by the portfolio, calculate two accrued interest factors:

- Calculate the first accrued interest factor using the most recent portfolio pricing date as the settlement date. Use this accrued interest factor (and the resulting market value including accrued interest) when calculating Market Value of Securities (B).
- Calculate the second accrued interest factor, and *all* analytics, using the settlement date convention of the index for this portfolio. Use this accrued interest factor (and the resulting market value including accrued interest) when calculating metrics such as the average duration of the portfolio.

Settlement Date Holdings: If a portfolio buys a security on trade date "T" for settlement in T + 3 business days, then this position is not included among the settlement date holdings for this portfolio as of the close on portfolio pricing date "T." This position is not included among the settlement date holdings for this portfolio until the close on the portfolio pricing date that corresponds to T + 3 business days.

Standard FX Trades: These include the following trades:

1. **Spot FX Trade:** Trade where the value date is zero to two business days after the trade date and the base currency of the portfolio (for example, USD) is one of the two currencies in the currency pair.
2. **Cross-Currency Spot FX Trade:** Trade where the value date is zero to two business days after the trade date and the base currency of the portfolio (for example, USD) is *not* one of the two currencies in the currency pair.
3. **FX Forward Outright:** Trade where the value date is more than two business days after the trade date and the base currency of the portfolio (for example, USD) is one of the two currencies in the currency pair.
4. **Cross-Currency FX Forward Outright:** Trade where the value date is more than two business days after the trade date and the base currency of the portfolio (for example, USD) is *not* one of the two currencies in the currency pair.
5. **FX Swap:** Trade where a trader negotiates and simultaneously executes a spot FX trade and an FX forward outright with the same dealer and the base currency of the portfolio (for example, USD) is one of the two currencies in the currency pair. (This swap never involves more than two currencies. The non–base currency in the short leg is always the same as the non-base currency in the long leg.)
6. **Cross-Currency FX Swap:** Trade where a trader negotiates and simultaneously executes a spot FX trade and an FX forward outright with the same dealer and the base currency of the portfolio (for example, USD) is *not* one of the two currencies in the currency pair. (This swap never involves more than two currencies. The currency pair in the short leg is always the same as the currency pair in the long leg. Whichever currency is bought in the short leg is always sold in the long leg. Similarly, whichever currency is sold in the short leg is always bought in the long leg.)

As of March 31, 2011, there were 14 currencies in the WGBI. Spot settlement for the Canadian dollar (CAD) is T + 1 business day. Spot settlement for the remaining 13 currencies is T + 2 business days.

(*Continued*)

EXHIBIT A–1

Defined Terms for Bond Portfolios (*Continued*)

Trade Date Holdings: If a portfolio buys a security on Trade Date "T" for settlement in T + 3 business days, then this position is included among the trade date holdings for this portfolio as of the close on portfolio pricing date "T."

Unsettled Bond Trades: These trades include all unsettled trades involving the types of instruments that are included in the securities held by the portfolio when calculating Market Value of Securities (B) for a portfolio.

Unsettled FX Trades: These trades include all of the unsettled standard FX trades.

Unsettled Trades: These trades include:

- Unsettled bond trades
- Unsettled FX trades

Inputs to the Main Formula for Bond Portfolios

Market Value of Securities (B)

In order to calculate this input, first calculate the market value (including accrued interest) for each of the securities held by the portfolio that is denominated in the single currency for which one is calculating the Currency Exposure (A). Then sum the resulting market values. The sum is the Market Value of Securities (B).

Cash Balance (C)

This is the cash balance in the single currency for which one is calculating the Currency Exposure (A). If the cash balance is not denominated in the base currency of the portfolio, then use the following formula:

Cash Balance = Contractual End of Day Cash Balance
on the Most Recent Portfolio Pricing Date

This cash balance should include all of the principal and interest payments that were scheduled to be received by the portfolio on or before the portfolio pricing date (whether or not they were actually received by the portfolio's custodial bank and credited to the portfolio). As a general rule, when the accrued interest included in the Market Value of Securities (B) drops to reflect a coupon payment (and the duration extends), then that coupon payment should be included in the Cash Balance (C) at the same point in time. (One exception is bonds that go *ex*-coupon.)

This cash balance should also reflect all of the bond trades and FX trades that were scheduled to settle on or before the portfolio pricing date (whether or not the bond trades and FX trades actually settled).

If the cash balance is denominated in the base currency of the portfolio, then use the following formula:

Cash Balance in the Base Currency = Adjusted Net Assets
– (first calculate the Currency Exposure (A) for each

non-base currency, then convert the resulting local
currency amount to the base currency of the portfolio,
and then sum the resulting base-currency amounts) – (Market Value
of Securities (B) for the base currency of the portfolio)
– (the sum of "D" through "R" for the base currency of the portfolio)

Thus, the cash balance in the base currency is a "plug" that can be calculated only after all of the other inputs have been calculated. This plug is useful for a number of reasons. For example, it causes the Currency Exposures (A), when converted to the base currency of the portfolio and then summed, to equal the net assets of the portfolio. In addition, the portfolio's exposure to each currency expressed as a percentage of net assets (i.e., as a percentage of the portfolio's overall market value) can be calculated. Summing the percentage of the market value for all of the currencies, they will sum to 100%. As a result, the currency exposures have the "portfolio property." (Contribution to duration is another example of a risk measure that has the portfolio property: Summing the contribution to duration made by each holding in a portfolio, the sum equals the average option adjusted duration for the overall portfolio.)

Unsettled Sells of Securities (D)

Identify all of the unsettled sells of securities that are denominated in the single currency for which one is calculating the Currency Exposure (A). Then sum the total proceeds for all of these trades. The resulting sum will be the Unsettled Sells of Securities (D). These unsettled sells of securities should include all bond trades (as opposed to FX trades) where the *scheduled* settlement date is after the portfolio pricing date. (If a trade was supposed to settle on or before the portfolio pricing date, but it "failed" to settle, then do not include that trade when summing the total proceeds.)

Unsettled Buys of Securities (E)

Identify all of the unsettled buys of securities that are denominated in the single currency for which one is calculating the Currency Exposure (A). Then sum the total proceeds for all of these trades. The resulting sum will be the Unsettled Buys of Securities (E). These unsettled buys of securities should include all bond trades (as opposed to FX trades) where the *scheduled* settlement date is after the portfolio pricing date. (If a trade was supposed to settle on or before the portfolio pricing date, but it "failed" to settle, then do not include that trade when summing the total proceeds.)

Unsettled Buys of Currency (F)

Identify all of the unsettled buys of currency that are denominated in the single currency for which one is calculating the Currency Exposure (A). Then calculate the present value of the currency amount on the value date for each FX trade. Then sum the present values for all of these trades. The resulting sum will be the

Unsettled Buys of Currency (F). These unsettled buys of currency should include all of the FX trades (including spot FX trades, FX forward outrights, and FX swaps) where the *scheduled* value date is after the portfolio pricing date. (If a trade was supposed to settle on or before the portfolio pricing date, but it "failed" to settle, then do not include that trade when summing the present values.)

When calculating the present value, use the currency amount on the value date for each FX trade, which is the currency amount that the portfolio will receive from the counterparty when the FX trade settles. In order to calculate the present value of the currency amount on the value date, see the definition for present value in Exhibit A–1.

Unsettled Sells of Currency (G)

Identify all of the unsettled sells of currency that are denominated in the single currency for which one is calculating the Currency Exposure (A). Then calculate the present value of the currency amount on the value date for each FX trade. Then sum the present values for all of these trades. The resulting sum will be the Unsettled Sells of Currency (G). These unsettled sells of currency should include all of the FX trades (including spot FX trades, FX forward outrights, and FX swaps) where the *scheduled* value date is after the portfolio pricing date. (If a trade was supposed to settle on or before the portfolio pricing date, but it "failed" to settle, then do not include that trade when summing the present values.)

When calculating the present value, use the currency amount on the value date for each FX trade, which is the currency amount that the portfolio will pay to the counterparty when the FX trade settles. In order to calculate the present value of the currency amount on the value date, see the definition for present value in Exhibit A–1.

Coupon Payments for Gilt Holdings (H)

Review the securities held by the portfolio and identify all of the interest-bearing gilt positions (and positions in other securities that go *ex*-coupon and thus can settle with a negative accrued interest). Then, among these positions, identify the positions that are denominated in the single currency for which one is calculating the Currency Exposure (A). Then, among these positions, identify the positions where the most recent portfolio pricing date falls after the *ex*-coupon date and before that coupon payment date. Calculate the payment amount (in the local currency) for each of these coupon payments. Sum these coupon payment amounts. The resulting sum will be the Coupon Payments for Gilt Holdings (H). (The sovereign debt securities of the United Kingdom are called "gilts." In this Appendix the term "gilts" is a short-hand way of referring to *all* securities that go *ex*-coupon and trade with a negative accrued interest.)

Coupon Payments for Unsettled Sells of Gilts (I)

Review the unsettled bond trades and identify all of the sells of interest-bearing gilts (and sells of other securities that go *ex*-coupon and thus can settle with a

negative accrued interest). Then, among these sells, identify the sells that are denominated in the single currency for which one is calculating the Currency Exposure (A). Then, among these sells, identify the sells where the most recent portfolio pricing date falls before a coupon payment date and the sell has a settlement date that falls after the *ex*-coupon date for that coupon payment date. Calculate the payment amount (in the local currency) for each of these coupon payments. Sum these coupon payment amounts. The resulting sum will be the Coupon Payments for Unsettled Sells of Gilts (I).

Coupon Payments for Unsettled Buys of Gilts (J)

Review the unsettled bond trades and identify all of the buys of interest-bearing gilts (and buys of other securities that go *ex*-coupon and thus can settle with a negative accrued interest). Then, among these buys, identify the buys that are denominated in the single currency for which one is calculating the Currency Exposure (A). Then, among these buys, identify the buys where the most recent portfolio pricing date falls before a coupon payment date and the buy has a settlement date that falls after the *ex*-coupon date for that coupon payment date. Calculate the payment amount (in the local currency) for each of these coupon payments. Sum these coupon payment amounts. The resulting sum will be the Coupon Payments for Unsettled Buys of Gilts (J).

Coupon Payments for Unsettled Sells of Non-Gilts (K)

Review the unsettled bond trades and identify all of the sells of interest-bearing securities that are not gilts (and that are not other securities that go *ex*-coupon and thus can settle with a negative accrued interest) and that are not Agency MBS (and that are not other securities that make delayed principal or interest payments). Then, among these sells, identify the sells that are denominated in the single currency for which one is calculating the Currency Exposure (A). Then, among these sells, identify the sells where the most recent portfolio pricing date falls before a coupon payment date and the sell has a settlement date that falls on or after that coupon payment date. Calculate the payment amount (in the local currency) for each of these coupon payments (and the accompanying principal payment, if there is one). Sum these payment amounts. The resulting sum will be the Coupon Payments for Unsettled Sells of Non-Gilts (K).

Coupon Payments for Unsettled Buys of Non-Gilts (L)

Review the unsettled bond trades and identify all of the buys of interest-bearing securities that are not gilts (and that are not other securities that go *ex*-coupon and thus can settle with a negative accrued interest) and that are not Agency MBS (and that are not other securities that make delayed principal or interest payments). Then, among these buys, identify the buys that are denominated in the single currency for which one is calculating the Currency Exposure (A). Then, among these buys, identify the buys where the most recent portfolio pricing date falls before a coupon payment date and the buy has a settlement date that falls

on or after that coupon payment date. Calculate the payment amount (in the local currency) for each of these coupon payments (and the accompanying principal payment, if there is one). Sum these payment amounts. The resulting sum will be the Coupon Payments for Unsettled Buys of Non-Gilts (L).

Interest Payments for Agency MBS Holdings (M)
Review the securities held by the portfolio and identify all of the U.S. agency mortgage-backed passthrough securities ("Agency MBS"). These are pools issued by Ginnie Mae, Fannie Mae, and Freddie Mac. Then, among these positions, identify the positions that are denominated in the single currency for which one is calculating the Currency Exposure (A). Then, among these positions, identify the positions where the most recent portfolio pricing date falls after an *ex*-coupon date (which is the last calendar day of a month) and before the corresponding interest payment date. Calculate the payment amount (in the local currency) for each of these interest payments. Sum these interest payment amounts. The resulting sum will be the Interest Payments for Agency MBS Holdings (M). (Use a similar approach for other securities that make delayed interest payments.)

Principal Payments for Agency MBS Holdings (N)
Review the securities held by the portfolio and identify all of the Agency MBS. Then, among these positions, identify the positions that are denominated in the single currency for which one is calculating the Currency Exposure (A). Then, among these positions, identify the positions where the most recent portfolio pricing date falls on or after the day on which factors and paydowns are processed for the portfolio and before the corresponding principal payment date. Calculate the payment amount (in the local currency) for each of these principal payments. Sum these principal payment amounts. The resulting sum will be the Principal Payments for Agency MBS Holdings (N). (Use a similar approach for other securities that make delayed principal payments.)

Interest Payments for Unsettled Sells of Agency MBS (O)
Review the unsettled bond trades and identify all of the sells of Agency MBS. Then, among these sells, identify the sells that are denominated in the single currency for which one is calculating the Currency Exposure (A). Then, among these sells, identify the sells where the most recent portfolio pricing date falls before an interest payment date and the sell has a settlement date that falls after the *ex*-coupon date for that interest payment date. Calculate the payment amount (in the local currency) for each of these interest payments. Sum these interest payment amounts. The resulting sum will be the Interest Payments for Unsettled Sells of Agency MBS (O). (Use a similar approach for other securities that make delayed interest payments.)

Principal Payments for Unsettled Sells of Agency MBS (P)
Review the unsettled bond trades and identify all of the sells of Agency MBS. Then, among these sells, identify the sells that are denominated in the single

currency for which one is calculating the Currency Exposure (A). Then, among these sells, identify the sells where the most recent portfolio pricing date falls on or after the day on which factors and paydowns are processed for the portfolio and before the corresponding principal payment date. Calculate the payment amount (in the local currency) for each of these principal payments. Sum these principal payment amounts. The resulting sum will be the Principal Payments for Unsettled Sells of Agency MBS (P). (Use a similar approach for other securities that make delayed principal payments.)

Interest Payments for Unsettled Buys of Agency MBS (Q)
Review the unsettled bond trades and identify all of the buys of Agency MBS. Then, among these buys, identify the buys that are denominated in the single currency for which one is calculating the Currency Exposure (A). Then, among these buys, identify the buys where the most recent portfolio pricing date falls before an interest payment date and the buy has a settlement date that falls after the *ex*-coupon date for that interest payment date. Calculate the payment amount (in the local currency) for each of these interest payments. Sum these interest payment amounts. The resulting sum will be the Interest Payments for Unsettled Buys of Agency MBS (Q). (Use a similar approach for other securities that make delayed interest payments.)

Principal Payments for Unsettled Buys of Agency MBS (R)
Review the unsettled bond trades and identify all of the buys of Agency MBS. Then, among these buys, identify the buys that are denominated in the single currency for which one is calculating the Currency Exposure (A). Then, among these buys, identify the buys where the most recent portfolio pricing date falls on or after the day on which factors and paydowns are processed for the portfolio and before the corresponding principal payment date. Calculate the payment amount (in the local currency) for each of these principal payments. Sum these principal payment amounts. The resulting sum will be the Principal Payments for Unsettled Buys of Agency MBS (R). (Use a similar approach for other securities that make delayed principal payments.)

MAIN FORMULA FOR CITIGROUP INDEXES

The following formula can be used to calculate the exposure to a single currency in a Citigroup multi-currency bond index:

Currency Exposure (A) =

Market Value of Securities (B)
+ Cash Balance (C)
– FX Forward Outright Sell (D)
+ FX Forward Outright Buy (E)

Currency Exposure (A)

This is the exposure that a Citigroup index has to a single currency as of the close on the index pricing date. This currency exposure is expressed in the local currency. It has not been converted to the base currency of the index. This main formula for Citigroup indexes can also be used to calculate the exposure to the base currency of the index.

There are four inputs that are needed in order to calculate this currency exposure. All of the four inputs should be expressed in the local currency. In other words, they should not be converted into the base currency of the index.

For the last two of these four inputs, one needs to calculate their present values before using them as inputs to the main formula for Citigroup indexes.

Inputs to the Main Formula for Citigroup Indexes

Market Value of Securities (B)

In general, one should use the same approach for indexes that one uses for portfolios. However, a few things will be different. For example, the securities in the index will be the securities that are in the current returns universe for the index. This data set should come directly from Citigroup. It should be updated each evening, in order to capture intra-month principal and interest payments that have been made by index constituents. Principal and interest payments will increase the cash balances in the current returns universe. Principal payments will lower the par amounts (or current faces) of the securities in the current returns universe.

In order to calculate this input, first calculate the market value (including accrued interest) for each of the securities in the index that is denominated in the single currency for which one is calculating the Currency Exposure (A). Then sum the resulting market values. The sum is the Market Value of Securities (B).

Cash Balance (C)

Citigroup will provide the cash balances for each currency. The Cash Balance (C) will be the cash balance in the single currency for which one is calculating the Currency Exposure (A); it will be the sum of the principal and interest payments received by the index on or after the *first* calendar day of the month and on or before the index settlement date used by Citigroup.

These cash balances should come directly from Citigroup. They should be updated each evening, in order to capture intra-month principal and interest payments that have been made by index constituents. Principal and interest payments will increase the cash balances in the current returns universe. Principal payments will lower the par amounts (or current faces) of the securities in the current returns universe. Note that as of the close on the last business day of a month, there is no cash in the returns universe for the coming month.

FX Forward Outright Sell (D)

Unhedged indexes do not contain any FX forward outright sells. As a result, for an unhedged index, set FX Forward Outright Sell (D) equal to zero, and move on.

The returns universe for a hedged version of a Citigroup index contains one FX forward outright sell for each foreign currency in the index. For each of these FX forward outright sells, Citigroup calculates the currency amount on the value date. Citigroup does this once a month at the beginning of the month, and provides this information to their clients via automated downloads. Citigroup has published two documents that together do a nice job of describing the hedging methodology used for the hedged versions of the Citigroup indexes; the first one is entitled *SSB Fixed Income Indices: Currency Hedging Methodology* (March 6, 2003) and the second one is entitled *Change in Spot Settlement Convention in the Currency Hedging Methodology* (January 6, 2011). Using the currency amount on the value date that Citigroup provides, one needs to calculate the present value of the currency amount. In order to do this, see the definition for present value in Exhibit A–2.

EXHIBIT A–2

Defined Terms for Citigroup Indexes

Accrued Interest: Always use the accrued interest provided by Citigroup.

Compounding Frequency: All analytics (including yield to worst) should be calculated assuming semiannual compounding. As of December 31, 2010, 75.3% of the securities in the WGBI (based on market value) paid coupons semiannually.

Exchange Rates—Closing Spot Rates: Use the following hierarchy in order to determine the closing spot rates for the Citigroup indexes:

- Books and records
- Citigroup
- WM/Reuters
- Bloomberg

Exchange Rates—Closing Forward Rates: Use the following hierarchy in order to determine the closing forward rates for the Citigroup indexes:

- Citigroup
- WM/Reuters
- Bloomberg

Ex-Coupon: When a security in a Citigroup index goes *ex*-coupon and starts trading with a negative accrued interest, Citigroup adds the coupon payment to the Cash Balance (C). However, there is no reinvestment return until the coupon payment is actually made on the coupon payment date. There were 23 countries in the WGBI as of March 1, 2011. Of these, the sovereign debt securities of the following six countries go *ex*-coupon and then trade with a negative accrued interest:

1. Australia
2. Norway
3. Poland
4. Singapore
5. Sweden
6. United Kingdom

(*Continued*)

EXHIBIT A–2

Defined Terms for Citigroup Indexes (*Continued*)

When these securities go *ex*-coupon, Bloomberg displays a negative accrued interest on BXT. There is one exception: when Poland's sovereign debt securities go *ex*-coupon, Bloomberg displays a zero accrued interest on BXT. However, Bloomberg takes the *ex*-coupon date into account when calculating price given yield.

Index Pricing Date: In general, one should always use the most recent index pricing date, because the most recent index pricing date will usually be the same date as the most recent portfolio pricing date. However, if the most recent index pricing date is a different date than the most recent portfolio pricing date, then there are two possibilities:

1. The most recent index pricing date is more recent than the most recent portfolio pricing date. In this case, if there is a previous index pricing date that falls on the same date as the most recent portfolio pricing date, then use that previous index pricing date. If not, then use the most recent index pricing date and remove books and records from the hierarchies used to determine the prices and exchange rates for the index.
2. The most recent index pricing date is older than the most recent portfolio pricing date. In this case, use the most recent index pricing date and remove books and records from the hierarchies used to determine the prices and exchange rates for the index.

Index Settlement Date: Use the following index settlement dates for the Citigroup indexes:

For all of the securities in the index, the index settlement date is T + 0 (except for the last business day of the month, when the index settlement date is the last calendar day of that month).

Note that T + 0 is always the index pricing date.

For each of the securities in a Citigroup index, use the index settlement date to calculate *all* of the analytics.

Market Value: In order to calculate the market value for each of the securities in the index, use the following formulas:

$$\text{Market Value} = \text{Principal} + \text{Accrued Interest}$$

$$\text{Principal} = \text{Par Amount} \times (\text{Price}/100)$$

Par Amount: For non-factoring securities, always use the par amount provided by Citigroup. For factoring securities, always use the current face provided by Citigroup.

Present Value: Calculate the present value for each unsettled FX trade where there are more than four business days between the index pricing date and the value date for the unsettled FX trade. For each unsettled FX trade, take both currencies in the currency pair into account and calculate the present value of the currency amount for each one separately. In order to calculate the present value of the currency amount, use the following formula:

$$PV = C/(1 + R/100 \times N/B)$$

PV = Present value of the currency amount

C = Currency amount on the value date

R = Interest rate expressed as a percentage per annum

N = Actual number of days from the index pricing date to the value date

B = Day count basis (usually either 360 or 365, depending on the currency)

EXHIBIT A–2

Defined Terms for Citigroup Indexes (*Continued*)

For most currencies, for the interest rate, one should use the Eurodeposit rate for funds deposited in that currency. These Eurodeposit rates are provided by Citigroup. In addition, these Eurodeposit rates can be obtained from market data services such as Bloomberg and Reuters. See *Citigroup Global Fixed-Income Index Catalog, 2011 Edition* (February 8, 2011); the Reuters Instrument Codes (RICs) used to obtain monthly yields (bid) for Eurodeposits are provided for 18 currencies on page 61.

Price: For each of the securities in the index (except U.S. agency mortgage-backed passthrough securities), use the following hierarchy in order to determine the price:

- Books and records
- Citigroup
- Bloomberg

For each of the securities in the index, the same price that is used to calculate the principal and market value should also be used to calculate *all* of the analytics. For the U.S. agency mortgage-backed passthrough securities in the index, use the price provided by Citigroup.

Securities in the Index: These are the securities that are in the current returns universe for the index. This data set should come directly from Citigroup. It should be updated each evening, in order to capture intra-month principal and interest payments that have been made by index constituents. Principal and interest payments will increase the cash balances in the current returns universe. Principal payments will lower the par amounts (or current faces) of the securities in the current returns universe.

FX Forward Outright Buy (E)

Unhedged indexes do not contain any FX forward outright buys. As a result, for an unhedged index, set FX Forward Outright Buy (E) equal to zero, and move on.

The returns universe for a hedged version of a Citigroup index will contain one FX forward outright buy for the base currency of the index (for example, USD). Citigroup will provide this information. Using the currency amount on the value date that Citigroup provides, one needs to calculate the present value of the currency amount. In order to do this, see the definition for present value in Exhibit A–2.

MAIN FORMULA FOR BARCLAYS CAPITAL INDICES

The following formula can be used to calculate the exposure to a single currency in a Barclays Capital multi-currency bond index:

Currency Exposure (A) =

Market Value of Securities (B)

+ Cash Balance (C)

– FX Forward Outright Sell (D)

+ FX Forward Outright Buy (E)

Currency Exposure (A)

This is the exposure that a Barclays Capital index has to a single currency as of the close on the index pricing date. This currency exposure is expressed in the local currency. It has not been converted to the base currency of the index. This main formula for Barclays Capital indices can also be used to calculate the exposure to the base currency of the index.

There are four inputs that are needed in order to calculate this currency exposure. All of the four inputs should be expressed in the local currency. In other words, they should not be converted into the base currency of the index.

For the last two of these four inputs, one needs to calculate their present values before using them as inputs to the main formula for Barclays Capital indices.

Inputs to the Main Formula for Barclays Capital Indices

Market Value of Securities (B)

In general, one should use the same approach for indices that one uses for portfolios. However, a few things will be different. For example, the securities in the index will be the securities that are in the current returns universe for the index. This data set should come directly from Barclays Capital. It should be updated each evening, in order to capture intra-month principal and interest payments that have been made by index constituents. Principal and interest payments will increase the cash balances in the current returns universe. Principal payments will lower the par amounts (or current faces) of the securities in the current returns universe.

In order to calculate this input, first calculate the market value (including accrued interest) for each of the securities in the index that is denominated in the single currency for which one is calculating the Currency Exposure (A). Then sum the resulting market values. The sum is the Market Value of Securities (B).

Cash Balance (C)

Barclays Capital will provide the cash balances for each currency. The Cash Balance (C) will be the cash balance in the single currency for which one is calculating the Currency Exposure (A); it will be the sum of the principal and interest payments received by the index on or after the *second* calendar day of the month and on or before the index settlement date used by Barclays Capital. There is one exception: estimated principal and interest payments generated by U.S. agency mortgage-backed passthrough securities are added to the USD cash balance at the close on the first calendar day of the month.

These cash balances should come directly from Barclays Capital. They should be updated each evening in order to capture intra-month principal and interest payments that have been made by index constituents. Principal and interest payments will increase the cash balances in the current returns universe. Principal payments will lower the par amounts (or current faces) of the securities

in the current returns universe. Note that as of the close on the last business day of a month, there is no cash in the statistics universe (which is the returns universe for the coming month).

FX Forward Outright Sell (D)

Unhedged indices do not contain any FX forward outright sells. As a result, for an unhedged index, set FX Forward Outright Sell (D) equal to zero, and move on.

Hedged indices contain one FX forward outright sell for each foreign currency in the index. Today, it is not possible to download these FX forward outright sells from Barclays Capital POINT, nor is it possible to see them on any screen, nor are they provided in any published reports. As a result, you need to calculate these amounts yourself. More specifically, you need to calculate the currency amount *on the value date* for each of the two currencies in each FX forward outright sell in each returns universe. You only have to do this once a month at the beginning of the month. A document entitled *A Guide to the Lehman Brothers Global Family of Indices* (March 2008) does a nice job of describing the hedging methodology used for the hedged versions of the Barclays Capital indices (pages 121–127). However, in order to exactly replicate the FX forward outright sells in each returns universe, one should ask the index group at Barclays Capital for specific guidance, as there are a number of nuances. Once you have calculated the currency amount on the value date for each of the two currencies in an FX forward outright sell, you need to calculate the present value of the currency amount for each of these two currencies. In order to do this, see the definition for present value in Exhibit A–3.

EXHIBIT A–3

Defined Terms for Barclays Capital Indices

Accrued Interest: Always use the accrued interest provided by Barclays Capital.

Compounding Frequency: All analytics (including yield to worst) should be calculated assuming semiannual compounding.

Exchange Rates—Closing Spot Rates: Use the following hierarchy in order to determine the closing spot rates for the Barclays Capital indices:

- Books and records
- Barclays Capital
- WM/Reuters
- Bloomberg

Exchange Rates—Closing Forward Rates: Use the following hierarchy in order to determine the closing forward rates for the Barclays Capital indices:

- Barclays Capital
- WM/Reuters
- Bloomberg

(*Continued*)

EXHIBIT A–3

Defined Terms for Barclays Capital Indices (*Continued*)

Ex-Coupon: When a security in a Barclays Capital index goes *ex*-coupon and starts trading with a negative accrued interest, Barclays Capital adds the coupon payment to the Cash Balance (C). The coupon payment is not reinvested until month end.

Index Pricing Date: In general, one should always use the most recent index pricing date, because the most recent index pricing date will usually be the same date as the most recent portfolio pricing date. However, if the most recent index pricing date is a different date than the most recent portfolio pricing date, then there are two possibilities:

1. The most recent index pricing date is more recent than the most recent portfolio pricing date. In this case, if there is a previous index pricing date that falls on the same date as the most recent portfolio pricing date, then use that previous index pricing date. If not, then use the most recent index pricing date and remove books and records from the hierarchies used to determine the prices and exchange rates for the index.
2. The most recent index pricing date is older than the most recent portfolio pricing date. In this case, use the most recent index pricing date and remove books and records from the hierarchies used to determine the prices and exchange rates for the index.

Index Settlement Date: Use the following index settlement dates for the Barclays Capital indices:

- For U.S. agency mortgage-backed passthrough securities, the index settlement date is T + 0 (except for the last business day of the month, when the index settlement date is the last calendar day of that month).
- For all securities other than U.S. agency mortgage-backed passthrough securities, the index settlement date is T + 1 calendar day (except for the last business day of the month, when the index settlement date is the first calendar day of the next month).

Note that T + 0 is always the index pricing date.

For each of the securities in the index, use the index settlement date to calculate *all* of the analytics.

Market Value: In order to calculate the market value for each of the securities in the index, use the following formulas:

$$\text{Market Value} = \text{Principal} + \text{Accrued Interest}$$

$$\text{Principal} = \text{Par Amount} \times (\text{Price}/100)$$

Par Amount: For non-factoring securities, always use the par amount provided by Barclays Capital. For factoring securities, always use the current face provided by Barclays Capital.

Present Value: Calculate the present value for each unsettled FX trade where there are more than four business days between the index pricing date and the value date for the unsettled FX trade. For each unsettled FX trade, take both currencies in the currency pair into account and calculate the present value of the currency amount for each one separately. In order to calculate the present value of the currency amount, use the following formula:

EXHIBIT A–3

Defined Terms for Barclays Capital Indices (*Continued*)

$PV = C/(1 + R/100 \times N/B)$

PV = Present value of the currency amount

C = Currency amount on the value date

R = Interest rate expressed as a percentage per annum

N = Actual number of days from the index pricing date to the value date

B = Day count basis (usually either 360 or 365, depending on the currency)

For most currencies, for the interest rate, one should use the Eurodeposit rate for funds deposited in that currency. These Eurodeposit rates are provided by Citigroup. In addition, these Eurodeposit rates can be obtained from market data services such as Bloomberg and Reuters. See *Citigroup Global Fixed-Income Index Catalog, 2011 Edition* (February 8, 2011); the Reuters Instrument Codes (RICs) used to obtain monthly yields (bid) for Eurodeposits are provided for 18 currencies on page 61.

Price: For each of the securities in the index (except U.S. agency mortgage-backed passthrough securities), use the following hierarchy in order to determine the price:

- Books and records
- Barclays Capital
- Bloomberg

For each of the securities in the index, the same price that is used to calculate the principal and market value should also be used to calculate *all* of the analytics. For the U.S. agency mortgage-backed passthrough securities in the index, use the price provided by Barclays Capital.

Securities in the Index: These are the securities that are in the current returns universe for the index. This data set should come directly from Barclays Capital. It should be updated each evening, in order to capture intra-month principal and interest payments that have been made by index constituents. Principal and interest payments will increase the cash balances in the current returns universe. Principal payments will lower the par amounts (or current faces) of the securities in the current returns universe.

FX Forward Outright Buy (E)

Unhedged indices do not contain any FX forward outright buys. As a result, for an unhedged index, set FX Forward Outright Buy (E) equal to zero, and move on.

Hedged indices contain one FX forward outright sell for each foreign currency in the index. The second currency in each of these FX forward outright sells is the base currency of the index, which the index is always buying one month forward. In order to calculate the FX Forward Outright Buy (E), first calculate the currency amount on the value date for each of the foreign currencies in the index (see FX Forward Outright Sell (D) above). Then use one-month forward exchange rates (POINT displays these) to calculate the currency amount on the value date for the base currency of the index. Then sum these currency amounts on the value date for the base currency of the index. Finally, calculate the present value of this summed currency amount. In order to do this, see the definition for present value in Exhibit A–3.
